FIG. 857.—Transverse section of peritoneum.

again to the stomach, as the lesser omentum, and thus it forms the anterior boundary of the foramen of Winslow. It now covers the front of the stomach, and

upon reaching the cardiac extremity it passes to the hilum of the spleen, forming the anterior layer of the gastro-splenic omentum. From the hilum of the spleen it can be traced over the surface of this organ, to which it gives a serous covering; it is then reflected from the posterior border of the hilum on to the left kidney, forming the posterior layer of the lieno-renal ligament.

Numerous folds, formed by the peritoneum, extend between the various organs or connect them to the parietes. These serve to hold the organs in position, and at the same time enclose the vessels and nerves proceeding to each part. Some of these folds are called **ligaments**, such as the ligaments of the liver and the false ligaments of the bladder. Others, which connect certain parts of the intestine with the abdominal wall, constitute the **mesenteries**; and lastly, those which proceed from the stomach to certain viscera in its neighborhood are called **omenta**.

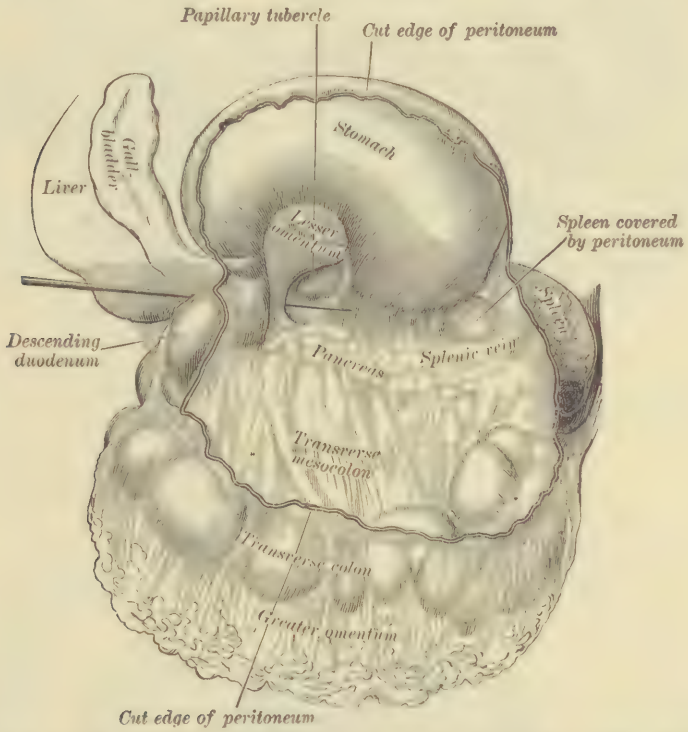

FIG. 858.—Bursa omentalis, opened from the front by an incision through the gastro-colic omentum. A probe passes through the foramen of Winslow and rests on the gastro-pancreatic fold. (Henle.)

The Ligaments of the Peritoneum.—The ligaments, formed by folds of the peritoneum, include those of the liver, spleen, bladder, and uterus. They will be found described with their respective organs.

The Omenta.—The omenta are: the **lesser omentum**, the **great omentum**, and the **gastro-splenic omentum**.

The **Lesser** or **Gastro-hepatic Omentum** (*omentum minus*) (Figs. 853 and 858) is the duplicature which extends between the transverse fissure of the liver and the right side of the abdominal portion of the oesophagus, the lesser curvature of the stomach, and the upper portion of the superior surface of the duodenum. The portion going to the oesophagus and stomach is called the **hepato-gastric ligament** (*ligamentum hepatogastricum*). The division of the ligament which goes to the oesophagus is strong and dense; the division which goes to the lesser curvature of the stomach is thin and relaxed. The portion of the lesser omentum which goes to the duodenum is continuous with the first-named portion. It is called the **hepato-**

duodenal ligament (*ligamentum hepatoduodenale*). The right margin of this ligament is free and concave. The **hepato-colic ligament** (*ligamentum hepatocolicum*) is not invariably present. It is a fold of the hepato-duodenal ligament and

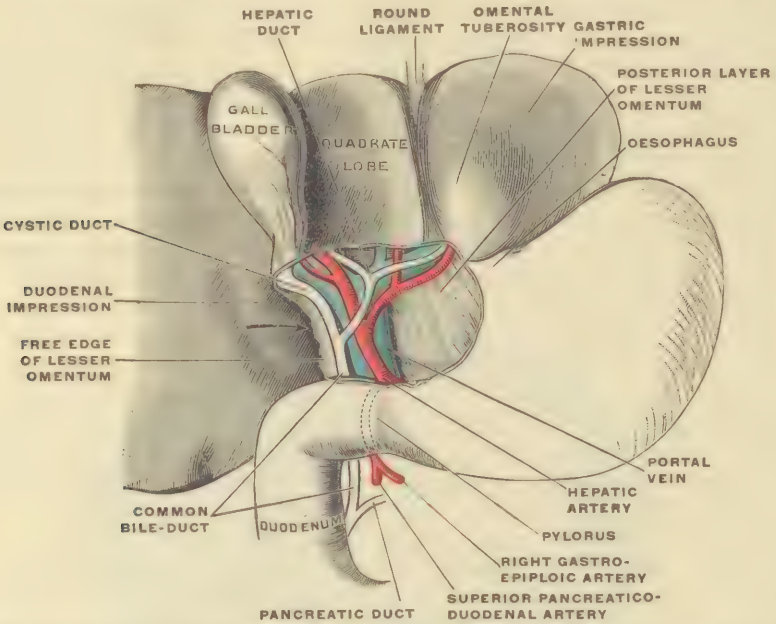

FIG. 859.—Structure between the layers of the lesser omentum. The liver has been raised up, and the anterior layer of the omentum removed. Semidiagrammatic. (Cunningham.)

runs from the posterior surface of the gall-bladder to the descending portion of the duodenum or possibly to the transverse colon. From the free margin of the termination of the hepato-duodenal ligament a fold often passes to the front

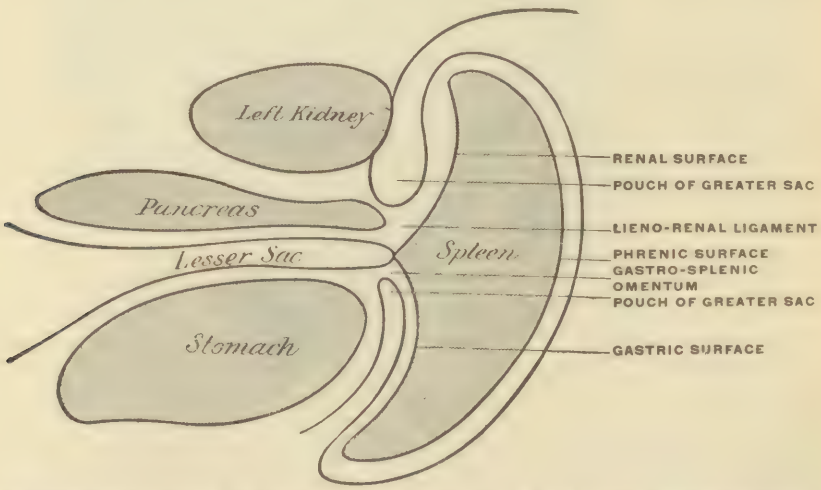

FIG. 860. Horizontal section through the stomach, pancreas, spleen, and the left kidney to show peritoneal reflections at the hilum of the spleen. (G. S. H.)

of the right kidney. It is known as the **duodeno-renal ligament** (*ligamentum duodenorenale*). The lesser omentum is extremely thin, and consists of two layers of peritoneum; that is, the two layers covering respectively the anterior and

posterior surfaces of the stomach. The posterior layer is part of the wall of the lesser peritoneal cavity; the anterior layer, of the greater peritoneal cavity. When the two layers reach the lesser curvature of the stomach, they join together and ascend as the double fold to the transverse fissure of the liver; to the left of this fissure the double fold is attached to the fissure of the ductus venosus as far as the Diaphragm, where the two layers separate to embrace the end of the oesophagus. At the right border the lesser omentum is free, and the two layers of which it is composed are continuous. The anterior layer, which belongs to the greater sac, turns around the hepatic vessels to become continuous with the posterior layer belonging to the lesser one. They here form a free, rounded margin, which contains between its layers the **hepatic artery,** the **common bile-duct,** the **portal vein, lymphatics,** and the **hepatic plexus of nerves** (Fig. 859)—all these structures being enclosed in loose areolar tissue, called **Glisson's capsule.** Between the layers where they are attached to the stomach lie the **gastric artery** and the **pyloric branch of the hepatic artery,** anastomosing with it. From the left side of the greater curvature of the stomach a fold passes to the gastric surface of the spleen, covers the spleen, and passes from the renal surface of the spleen around the left kidney to the Diaphragm.[1] The fold passing to the spleen is known as the **gastro-splenic ligament** or the **gastro-splenic omentum** (*ligamentum gastrolienale*) (Fig. 860). The portion passing to the Diaphragm is known as the **splenophrenic ligament** (*ligamentum phrenicolienale*). The **gastric veins** or **vasa brevia** pass from the left side of the greater curvature of the stomach toward the spleen in the gastro-splenic omentum.

The **Great** or **Gastro-colic Omentum** (*omentum majus*) (Figs. 853 and 861) is the largest peritoneal fold. It consists of four layers of peritoneum, two of which descend from the stomach, one from its anterior, the other from its posterior surface, and, uniting at its lower border, descend in front of the small intestines, sometimes as low down as the pelvis; they then turn upon themselves, and ascend again as far as the transverse colon, where they separate and enclose that part of the intestine. These separate layers may be easily demonstrated in the young subject, but in the adult they are more or less inseparably blended. At the free margins the two outer layers and the two inner layers become continuous. The left border of the great omentum is continuous with the gastro-splenic omentum; its right border extends as far only as the duodenum. The great omentum is usually thin, presents a cribriform appearance, and always contains some adipose tissue, which in fat subjects accumulates in considerable quantity. Between its two anterior layers is the anastomosis between the right and left gastro-epiploic arteries. In opening the abdomen the great omentum is rarely found spread out evenly over the intestines. It often projects between intestinal coils, or is largely gathered in some one region, or is pushed in front of the stomach by distention of the colon.

The lower portion of the lesser sac of the peritoneum continues for a distance between the ascending and descending layers of the great omentum (Fig. 853). The portion of the lesser peritoneal cavity within the great omentum is more or less obliterated in the adult by adhesion between its opposing layers. At birth the omentum is very short and barely reaches the umbilicus. In adults its length varies greatly. In some individuals it is very short; in others it passes into the pelvis. Mr. Lockwood points out that in persons under forty-five years of age the omentum can rarely be pulled down below the level of the pubic spine; in older persons it generally can.

The **Gastro-splenic Omentum** is the fold which connects the margins of the hilum of the spleen to the *cul-de-sac* of the stomach, being continuous by its lower

[1] Spalteholz, Hand Atlas of Human Anatomy. Translated and edited by Prof. Lewellys F. Barker.

border with the great omentum. It was described as the gastro-splenic ligament (Fig. 860).

The Mesenteries.—The mesenteries are: the **mesentery proper**, the **transverse mesocolon**, the **sigmoid mesocolon**, the **mesorectum** (p. 1259), and the **mesentery of the vermiform appendix**. In addition to these there are sometimes present an ascending and a descending mesocolon.

The **Mesentery** (*mesenterium*) (*μέσον ἔντερον*) (Figs. 853, 862, and 863), so called from being connected to the middle of the cylinder of the small intestine, is the broad fold of peritoneum which connects the convolutions of the jejunum and ileum with the posterior wall of the abdomen. It consists of a layer of connective tissue, each side of which is covered with peritoneum. In the connective

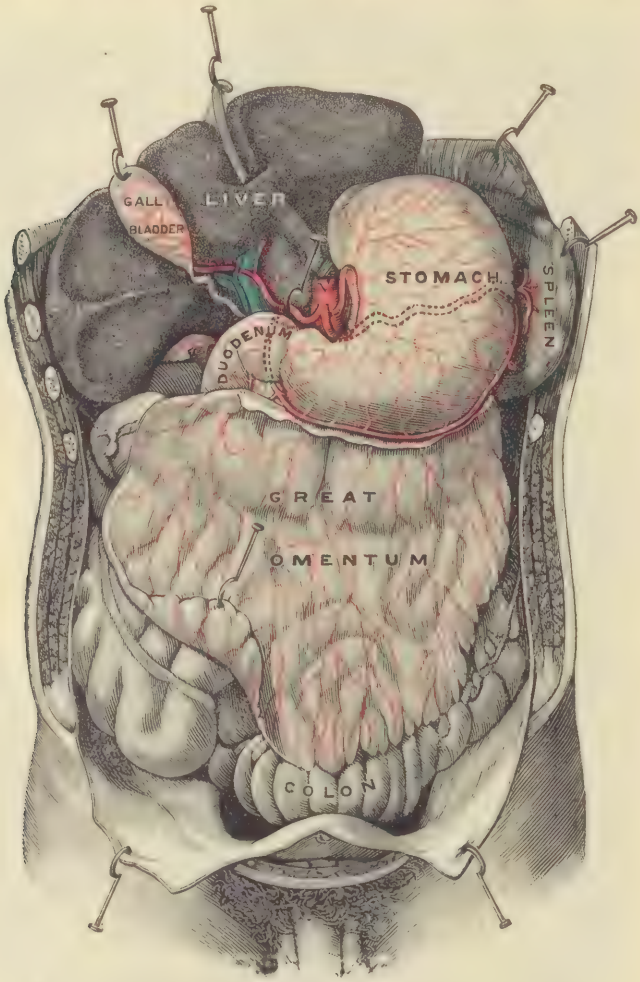

FIG. 861.—The great omentum as seen from the front. (Testut.)

tissue there are fatty masses. Its **root** (*radix mesenterii*), the part connected with the vertebral column, is narrow, about six inches in length, and directed obliquely from the left side of the second lumbar vertebra to the right sacro-iliac symphysis (Fig. 863). Its **intestinal border** is vastly broader (measures about twenty feet); and here its two layers separate so as to enclose the intestine, and form its peritoneal coat. Its breadth, between its vertebral and intestinal border, is about eight inches. Its **upper border** is continuous with the under surface of the transverse mesocolon; its **lower border**, with the peritoneum covering the caecum and

ascending colon. The origin of the mesentery *above* is just beyond the termination of the duodenum, and it terminates below in the angle formed by the junction of the ileum and the colon. It serves to retain the small intestines in their position, and contains between its layers the **mesenteric vessels** and **nerves**, the **lymphatic vessels** and **mesenteric glands**. These glands number from 50 to 150. Occasionally **congenital mesenteric openings** exist. In stout individuals the mesentery contains much fat. If there is much fat the mesentery is not translucent; if there is little fat it is translucent. It may be actually transparent above and translucent or opaque below. The thinnest part of the mesentery is above. As we descend it becomes thicker, because of the presence of fat, fibrous ligament, and muscular tissue.[1]

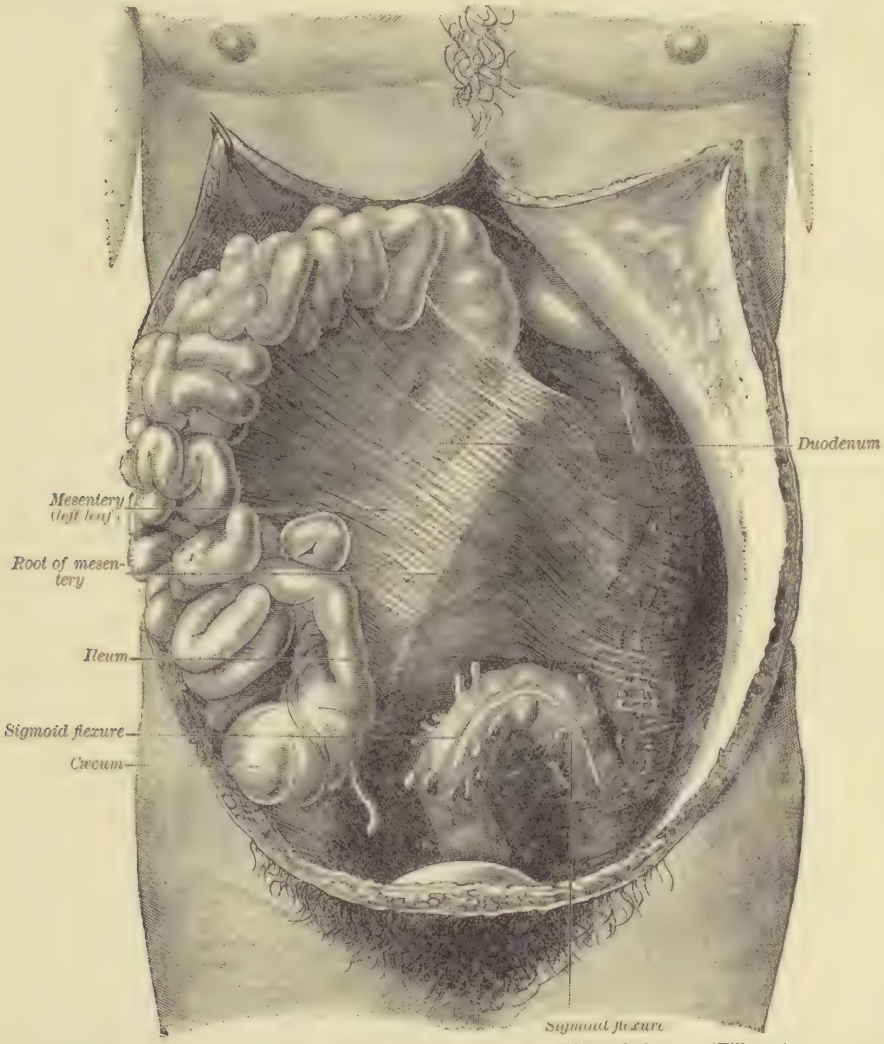

FIG. 862.—Mesentery. Small intestine pushed to the right and above. (Tillaux.)

In most cases the peritoneum covers only the front and sides of the ascending and descending parts of the colon. Sometimes, however, these are surrounded by the serous membrane and attached to the posterior abdominal wall by an **ascending mesocolon** (*mesocolon ascendens*) and a **descending mesocolon** (*mesocolon descendens*)

[1] Intestinal Localization. By Geo. H. Monks, Annals of Surgery, October, 1903.

respectively. At the place where the transverse colon turns downward to form the descending colon, a fold of peritoneum is continued to the under surface of the Diaphragm opposite the tenth and eleventh ribs. This is the **phreno-colic ligament** (*ligamentum phrenicocolicum*); it passes below the spleen, and serves to support this organ, and therefore it has received the second name of **sustentaculum lienis.**

The **Transverse Mesocolon** (*mesocolon transversum*) (Fig. 863) is a broad fold, which connects the transverse colon to the posterior wall of the abdomen. It is formed by the two ascending or posterior layers of the great omentum, which, after

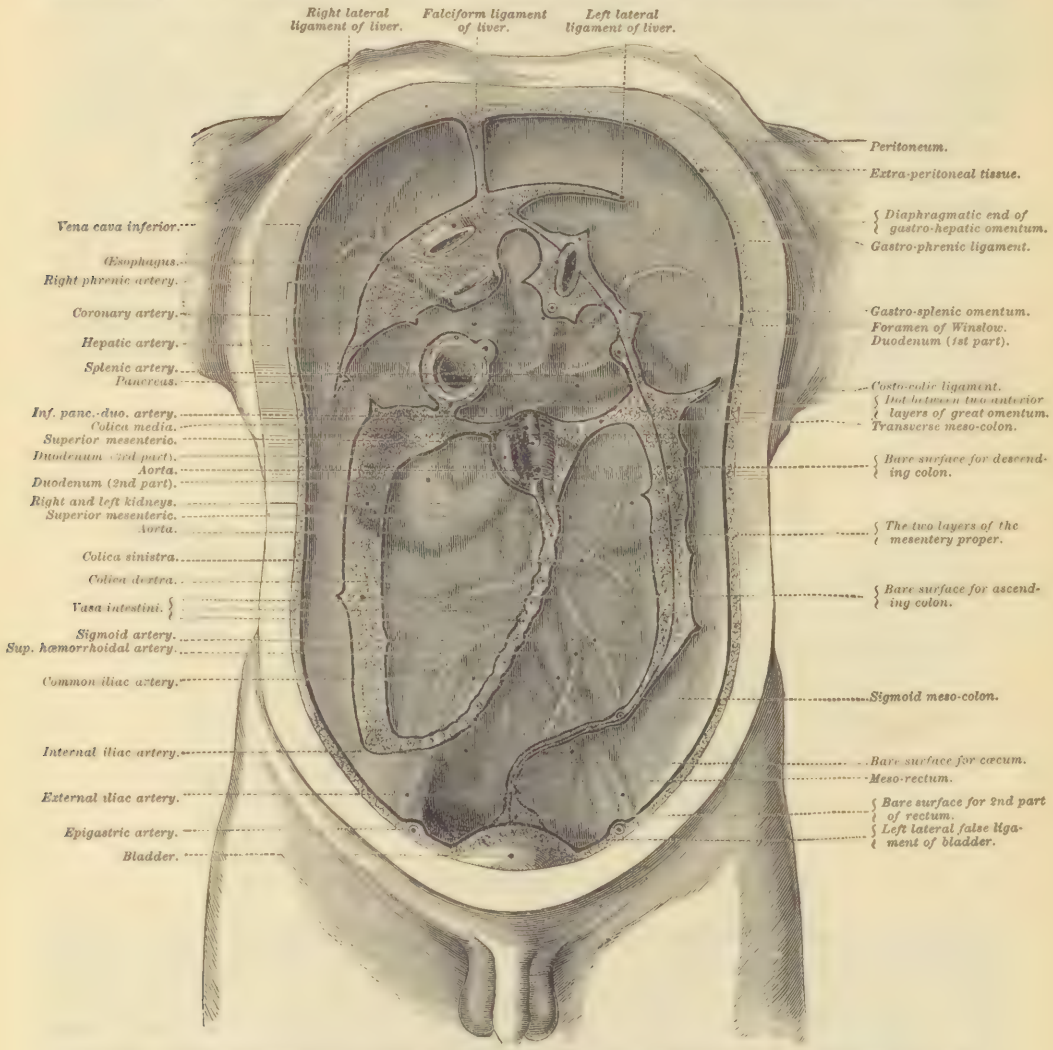

FIG. 863.—Diagram devised by Dr. Delépine to show the lines along which the peritoneum leaves the wall of the abdomen to invest the viscera.

separating to surround the transverse colon, join behind it, and are continued backward to the spine, where they diverge in front of the duodenum. This fold contains between its layers the vessels which supply the transverse colon.

The **Sigmoid Mesocolon** (*mesocolon sigmoideum*) (Fig. 863) is the fold of peritoneum which retains the sigmoid flexure in connection with the left iliac fossa. This portion of intestine remains always freely movable.

The **Mesorectum** is really only the lower portion of the sigmoid mesocolon. It is the name formerly given to the narrow fold which, according to the old defini-

tion of the rectum, connects the upper part of the rectum with the front of the sacrum. It contains the superior hemorrhoidal vessels.

The **Mesoappendix** or **Mesentery of the Vermiform Appendix** (*mesenteriolum processus vermiformis*) (Fig. 867) is a double fold of peritoneum which usually completely surrounds the vermiform appendix. It is usually described as a triangular fold, and at a glance it appears so, but Jonnesco points out that it has four borders: a *superior* or mesenteric border; a *right* or cæcal; a *left* or free, and an *inferior* or appendicular. One of the borders is often extremely short. The upper surface of the mesoappendix is continuous with the lower surface of the mesentery proper and with the left or internal fold of the peritoneum covering the caecum. The lower surface of the mesoappendix is continuous with the right or external fold of peritoneum covering the caecum. As a rule, the entire appendix is covered with peritoneum; sometimes a portion of the base is uncovered, and this portion of the diverticulum is then extraperitoneal. The tip is never extraperitoneal. The mesoappendix may be attached to the entire length of the appendix, but, as a rule, the tip is free. In fact, one-third, one-half, or two-thirds may be free and occasionally the mesoappendix is a mere vestige. Between the two peritoneal layers of the mesoappendix there is connective tissue, and often fat. In the connective tissue are the **appendicular blood-vessels, lymph-vessels,** and **nerves.**

The **Appendices Epiploicae** are small pouches of the peritoneum filled with fat and situated along the colon and upper part of the rectum. They are chiefly appended to the transverse colon.

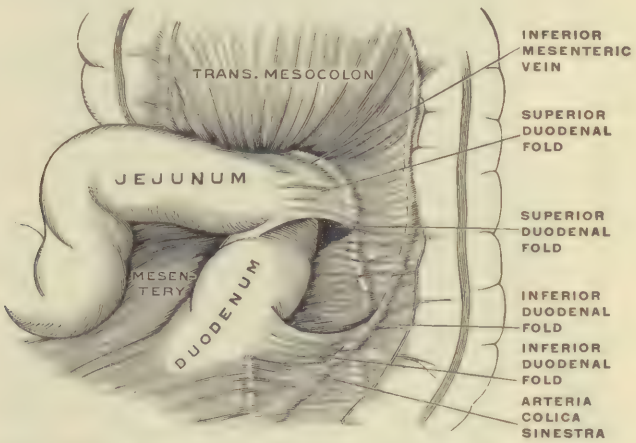

FIG. 864.—Superior and inferior duodenal fossa. (Poirier and Charpy.)

Retro-peritoneal Fossae.—In certain parts of the abdominal cavity there are recesses of peritoneum forming *culs-de-sac* or pouches, which are of surgical interest in connection with the possibility of the occurrence of retro-peritoneal hernia. One of these, which was previously described, is the **lesser sac of the peritoneum** (Figs. 853 and 855), which may be regarded as a recess of peritoneum through the foramen of Winslow, in which a hernia may take place, but there are several others, of smaller size, which require mention.

These recesses of fossae may be divided into three groups, viz.: (1) the **duodenal fossae**; (2) **pericæcal fossae**; and (3) the **intersigmoid fossa.**

1. **Duodenal Folds and Fossae.**—Moynihan has described no less than nine fossae as occurring in the neighborhood of the duodenum. Three of these are fairly constant. Five of the fossae are here considered. (*a*) The **inferior duodenal fossa** or **fossa of Treitz** (Fig. 864) is the most constant of all the peritoneal fossae in this region, being present in from 70 to 75 per cent. of cases. It is situated

opposite the third lumbar vertebra on the left side of the ascending portion of the duodenum. The opening into the fossa is directed upward, and is bounded by a thin, sharp fold of peritoneum with a concave free upper margin. This fold of peritoneum is called the **inferior duodenal fold** (*plica duodenomesocolica*). The tip of the index finger introduced into the fossa under the fold passes some little distance up behind the ascending or fourth portion of the duodenum. One margin of the fold is attached to the ascending portion of the duodenum; another margin is attached to the parietal peritoneum. (*b*) The **superior duodenal fossa** (Fig. 864) is the next most constant pouch or recess, being present in from 40 to 50 per cent. of cases. It often coexists with the inferior one, and its orifice looks downward, in the opposite direction to the preceding fossa. It lies to the left of the ascending portion of the duodenum. It is bounded in front by the **superior duodenal fold** (*plica duodenojejunalis*), which is triangular and has a free semilunar base; to the

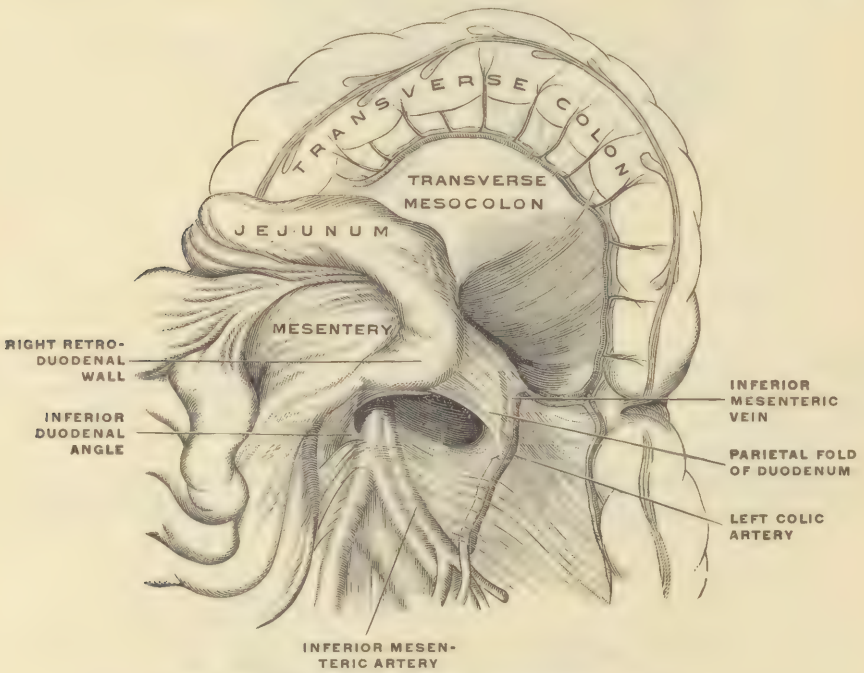

FIG. 865.—Retro-duodenal fossa. (Poirier and Charpy.)

right it is blended with the peritoneum covering the ascending duodenum, and to the left with the peritoneum covering the perirenal tissues. The fossa is bounded in front by the superior duodenal fold; behind by the second lumbar vertebra; to the right by the duodenum. Its depth is 2 cm., and it terminates in the angle formed by the left renal vein crossing the aorta. This fossa is of importance, as it is in relation with the inferior mesenteric vein; that is to say, the vein almost always corresponds to the line of union of the superior duodenal fold with the posterior parietal peritoneum. (*c*) The **duodeno-jejunal fossa** or **mesocolic fossa** (*recessus duodenojejunalis*) is formed where the duodeno-jejunal angle enters the root of the transverse mesocolon. There are two forms: (1) a single fossa and (2) a double fossa. It can be seen by pulling the jejunum downward and to the right, after the transverse colon has been pulled upward. It will appear as an almost circular opening, looking downward and to the right, and bounded by two free borders or folds of peritoneum, the **duodeno-mesocolic ligaments.** The opening admits the little finger into the fossa to the depth of from 2 to 3 cm. The fossa

is bounded above by the pancreas, to the right by the aorta, and to the left by the kidney; beneath is the left renal vein. The fossa exists in from 15 to 20 per cent. of cases, and has never yet been found in conjunction with any other form of duodenal fossa. (*d*) **Paraduodenal fossa** or the **fossa of Landzert** (*recessus duodenojejunalis*) is most distinct in the infant, and is to the left of the ascending portion of the duodenum. The fold of peritoneum to its outer side and above is

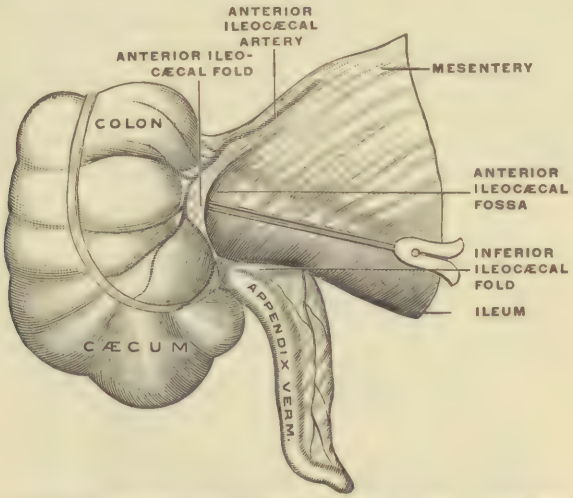

FIG. 866.—Anterior, sometimes called superior, ileo-cæcal fossa. (Poirier and Charpy.)

produced by the inferior mesenteric vein. Its lower limit is a fold called the **mesenterico-mesocolic fold.** (*e*) The **retroduodenal fossa** (Fig. 865) was described in 1893 by Jonnesco. It is a peritoneal *cul-de-sac*, sometimes found behind the horizontal and ascending portions of the duodenum.

2. **Pericæcal Folds and Fossae.**—There are at least three pouches or recesses to be found in the neighborhood of the caecum, which are termed **pericæcal fossae.** (1)

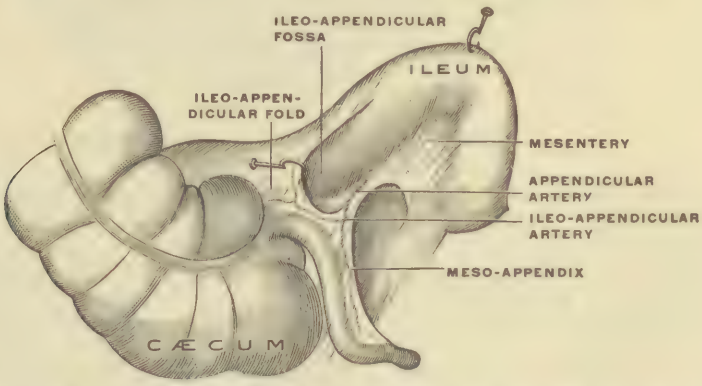

FIG. 867.—Ileo-appendicular or inferior ileo-cæcal fossa. The caecum and ascending colon have been drawn outward and downward, the ileum upward and backward, and the appendix downward. (Poirier and Charpy.)

The **ileo-colic fossa** or **superior ileo-cæcal** (*recessus ileocaecalis superior*) (Fig. 866) is formed by a fold of peritoneum, the **ileo-colic fold,** arching over a branch of the ileo-colic artery, which supplies the ileo-colic junction, and appears to be the direct continuation of the artery. The fossa is a narrow chink situated between the ileo-colic fold in front, and the mesentery of the small intestine, the ileum,

and a small portion of the caecum behind. (2) The **ileo-cæcal, inferior ileo-cæcal** or **ileo-appendicular fossa** (*recessus ileocaecalis inferior*) (Fig. 867) is situated behind the angle of junction of the ileum and caecum. It is formed by a fold of peritoneum, the **ileo-cæcal fold** (*plica ileocaecalis*), which Treves called the "bloodless fold." Tuffier denies its non-vascularity, and Lockwood and Rolleston state that it contains fat, muscular fibres, and arteries and veins derived from the appendicular vessels and the anterior and posterior ileo-cæcal vessels.[1] The upper border of the fold is attached to the ileum, opposite its mesenteric attachment, and the lower border, passing over the ileo-cæcal junction, joins the mesentery of the appendix, and sometimes the appendix itself; hence this fold is sometimes called the **ileo-appendicular fold.** Between the ileo-cæcal fold and the mesentery of the vermiform appendix is the **ileo-cæcal fossa.** It is bounded *above* by the posterior surface of the ileum and the mesentery; in *front* and *below* by the ileo-cæcal fold, and *behind* by the upper part of the mesentery of the appendix. (3) The **retro-cæcal** or **retro-colic**

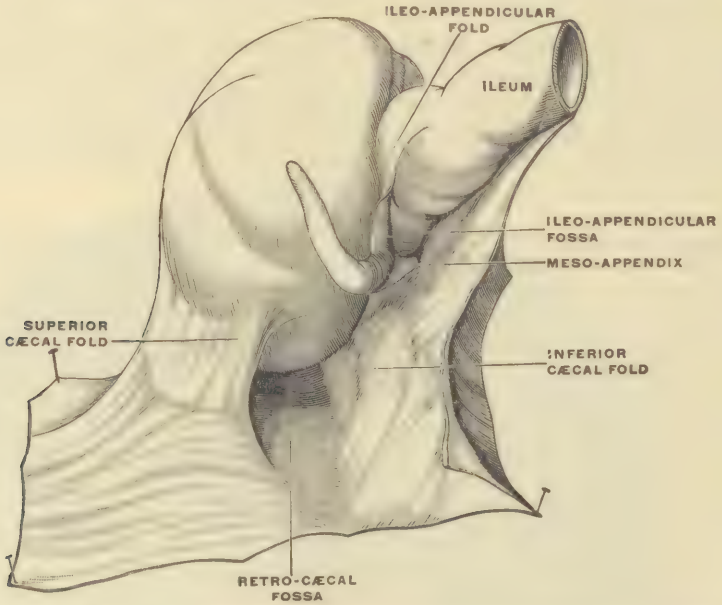

FIG. 868.—The retro-cæcal fossa. The ileum and cæcum are drawn backward and upward. (Souligoux.)

fossae (*recessus retrocaecalis*) (Fig. 868) are situated behind the caecum and ascending colon. There may be no fossa present. There may be one fossa; there are usually two (external and internal retrocolic fossae); occasionally there are more than two.[2] The fossae are brought into view by raising the caecum. According to Berry, one or other of the fossa is present in 30 per cent. of cases. Treves thinks the retrocolic fossae are extremely rare. There may be one fossa (20 per cent. of cases) or two fossae (10 per cent. of cases). If there is but one fossa it is the internal that exists three times as often as the external. The retro-colic space, if present, varies much in size and extent. In some cases it is sufficiently large to admit the index finger and extends upward behind the ascending colon in the direction of the kidney; in others it is merely a shallow depression. The **external retro-colic fossa** is bounded and formed by two folds: one, the **external parieto-colic fold** or the **superior cæcal fold,** which is the outer layer of the ascending mesocolon, and is attached by one edge to the abdominal wall from the lower border of the kidney to the iliac fossa and by the other to the postero-

[1] The Cæcal Folds and Fossae. By Richard J. A. Berry. [2] Ibid.

external aspect of the colon; and the other, the **internal parieto-colic fold** or **inferior cæcal fold,** which is the inner layer of the ascending mesocolon. The **internal retrocolic fossa** is bounded externally by the internal parieto-colic fold, and is bounded internally by the **mesenterico-parietal fold,** which is the insertion of the mesentery into the iliac fossa.

3. **The Intersigmoid Fossa** (*recessus intersigmoideus*).—The intersigmoid fossa is constant in the fœtus and common during infancy, but disappears in a large percentage of cases as age advances. Upon drawing the sigmoid flexure upward, the left surface of the sigmoid mesocolon is exposed, and on it will be seen a funnel-shaped recess of the peritoneum, lying on the external iliac vessels, in the interspace between the Psoas and Iliacus muscles. This is the orifice leading to the fossa intersigmoidea, which lies behind the sigmoid mesocolon, and in front of the parietal peritoneum. This fossa is produced by the incomplete fusion in the fœtus of the descending mesocolon with the parietal peritoneum. The fossa varies in size; in some instances it is a mere dimple, whereas in others it will admit the whole of the index finger.

Any of these fossæ may be the site of a **retro-peritoneal hernia.** The pericæcal fossæ are of especial interest, because hernia of the vermiform appendix frequently takes place into one of them, and may there become strangulated. The presence of these pouches also explains the course which pus has been known to take in cases of perforation of the appendix, where it travels upward behind the ascending colon as far as the Diaphragm.[1]

Surgical Anatomy.—Study of the lymphatics of the peritoneum by Byron Robinson and others shows that *absorption* takes place most rapidly from the region of the Diaphragm, less rapidly but still very actively from the region of the small intestine, slowly from the pelvic region. Clinically we know that pelvic peritonitis is not nearly so dangerous as peritonitis in the small intestine or Diaphragm areas, and that peritonitis in the region of the Diaphragm is the most fatal form of the infection. After *abdominal operations* in infected cases, it is well to elevate the head of the bed (*Fowler's position*), so as to obtain the aid of gravity in draining septic fluids away from the dangerous region and toward the safer region.[2] In areas in which absorption is rapid, protective exudation is not apt to form. In areas in which absorption is slow, inflammatory exudation is apt to circumscribe the area and prevent diffusion. After an operation in a non-infected case, if salt solution has been left in the abdominal cavity because of *shock* or *hemorrhage*, raising the foot of the bed will aid rapid absorption of the fluid by favoring the natural current toward the Diaphragm and hurrying the fluid to a region in which absorption is rapid.

The *great omentum* stores up fat, and, being movable, it is able to pass to different parts of the peritoneal cavity. Dr. Byron Robinson, in his work on the *Peritoneum*, describes its functions as follows: "The omentum is the great protector against peritoneal infectious invasions. It builds barriers of exudates to check infection. It is like a man-of-war, ready at a moment's notice to move to invaded parts. It circumscribes abscesses; it repairs visceral wounds, and prevents adhesions of mobile viscera to the anterior abdominal wall. It resists infectious invasions by typical peritoneal exudates, and not by succumbing to absorbed sepsis. It is a director of peritoneal fluids, a peritoneal drain."

In *abdominal wounds* the omentum often protrudes: This structure frequently constitutes or is part of a *hernia*, and is almost invariably present in umbilical hernia. As a result of *inflammation*, it may become adherent to adjacent structures. *Adhesions* may be of service by matting together the intestines and circumscribing infections. They may be harmful by constricting the bowels and producing obstruction. A portion of the omentum may become adherent to some other part and form a *band*, and under this band the gut may be caught and *strangulated*. Omentum may adhere to and plug a perforation in a hollow viscus, and the surgeon may utilize it for the same purpose, or to cover a raw surface or overlie a suture line. The omentum may be in the surgeon's way while operating. If it is, the patient is placed in the *Trendelenburg position* (pelvis elevated).

Any *tear* or opening found by the surgeon in the great omentum must be closed with sutures, because of the danger that intestine might enter and be caught in such an opening. A tumor cut off from its proper blood-supply, for instance, an ovarian cyst with a twisted pedicle, may continue to receive nourishment from adherent omentum, and gangrene may thus be prevented.

[1] On the anatomy of these fossæ, see the Arris and Gale Lectures by Moynihan, 1899.
[2] George R. Fowler, in Medical Record, April 14, 1900.

The lax character and shifting tendency of the subserous tissue explains the occurrence of *ptosis of the abdominal viscera and kidneys.*

The vast number of nerves in the peritoneum accounts for the profound shock which follows a wound, attends an intraperitoneal calamity, or which develops from infection. An infective process of any portion of the peritoneum produces pain and reflex symptoms (vomiting, abdominal rigidity, intestinal paresis, etc.).

The parietal peritoneum is very sensitive to pain, but not to touch; hence, after injecting a local anæsthetic and opening the abdomen, a fairly satisfactory exploration can be made with the finger.

The intestine, the mesentery, the stomach, the anterior margin of the liver, and the gall-bladder are insensitive, and may be cut or even burned without pain.[1]

Viscera which obtain their innervation purely from visceral nerves are insensitive; those which receive branches from somatic nerves are sensitive (Lennander).

The oblique origin of the mesentery causes this structure to form a sort of shelf. A hemorrhage or extravasation into the abdomen, to the right of the mesentery, tends to flow into the right iliac fossa; one occurring on the left side flows into the pelvis. Monks points out that in flushing the abdominal cavity the tube should not be aimlessly introduced, but should utilize the mesentery on each side of an intestinal loop, to "conduct the tip of the irrigating tube to the bottom of the two fossae."[2] Monks also shows how the mesentery can be utilized to determine the direction of an intestinal loop:

"Now, let us suppose that the surgeon has between his fingers a loop of bowel, and wishes to determine its direction. He knows that one side of the loop is the left side of the intestine, and that the corresponding side of the mesentery, if closely followed down to the mesenteric root, will conduct him into the left fossa; he also knows that the other side of the bowel is its right side, and that the mesentery on that side will conduct him into the right fossa. Now,

FIG. 869.—A loop of intestine, the middle of which is exactly three feet from the end of the duodenum. The gut is of large size. The mesenteric loops are primary, and the vasa recta large, long, and regular in distribution. The translucent spaces (lunettes) between the vessels are extensive. Below, the mesentery is streaked with fat. The veins, which had a distribution similar to the arteries, are for simplicity omitted from this and from the subsequent drawings. (The subject from which the specimen was taken was a male aged forty years, with rather less than the usual amount of fat. The entire length of the intestine was twenty-three feet. (Monks.)

if his finger goes into the great fossa on the left side of the abdomen, after having closely followed the mesentery down to its root and arranged his loop to be parallel with that root, he then knows that the left and right sides of the intestine face to the left and right sides of the abdomen respectively, and that the end of the loop which points downward is the end nearest the ileocæcal valve. He can determine the direction of the gut in a similar way in case his finger enters the right fossa. All this would seem very simple were it not for the twists in mesentery and intestine, which tend to mislead one. A little practice will usually enable one to recognize a twist in the mesentery. This should be untwisted by rotation of the gut, after which the direction is determined by another palpation of the mesenteric root."[3]

[2] Intestinal Localization, by George H. Monks, Annals of Surgery, October 1903.

[3] Annals of Surgery, October, 1903.

The studies made of the arrangement and variations of the loops of the mesenteric vessels by Dr. Thomas Dwight[1] have been utilized and expanded by Dr. George H. Monks in laying down

FIG. 870.—A loop of intestine at six feet. As compared with Fig. 869 the gut is somewhat smaller. The vascularity of the intestine and mesentery is less. Secondary loops are a prominent feature. The vasa recta are smaller. The lunettes are also present, but are not so large as in Fig. 869. (The subject was a male aged about thirty-five years, with an average amount of fat. The entire length of the intestine was twenty feet. (Monks.)

rules for the determination of the exact portion of small intestine which may be in the surgeon's hand.[2] His views are as follows:

"*General Vascularity of the Mesentery near the Bowel.*—Opposite the upper part of the bowel the mesenteric vessels are distinctly larger than opposite any other part of it. These vessels grow

FIG. 871.—A loop of intestine at nine feet. The secondary loops are large; the vasa recta are somewhat irregular and show branches. No lunettes are present, and the mesentery is streaked with fat, and is, therefore, somewhat opaque. (The specimen was taken from the same subject which furnished Fig. 869. (Monks.)

smaller and smaller as we pass downward until the lower third of the gut is reached, where they remain about the same size as far as the ileo-cæcal valve. The arrangement of the mesenteric

[1] Reports of the Meeting of American Anatomists, 1897.

[2] Annals of Surgery, 1903.

vessels has some features which intimately concern the subject in hand, and which I shall describe with some detail. Diagrammatically speaking, the main branches of the superior mesenteric artery unite with each other by means of loops, which are called for convenience 'primary loops;' in some parts of the tube, 'secondary loops,' and even, occasionally, 'tertiary loops' are super-

FIG. 872.—A loop of intestine at twelve feet. The vessels are smaller. The primary loops are lost in the fat, but secondary and even tertiary loops are visible. The vasa recta are shorter, more irregular, and branching. (The specimen came from the same subject which furnished Figs. 869 and 871.) (Monks.)

imposed upon these. From these loops little straight vessels—the vasa recta already referred to—run to the bowel, upon which they ramify, alternating, as a rule, as to the side of the intestine which they supply. The mesenteric veins are arranged in a manner somewhat similar to the arteries.

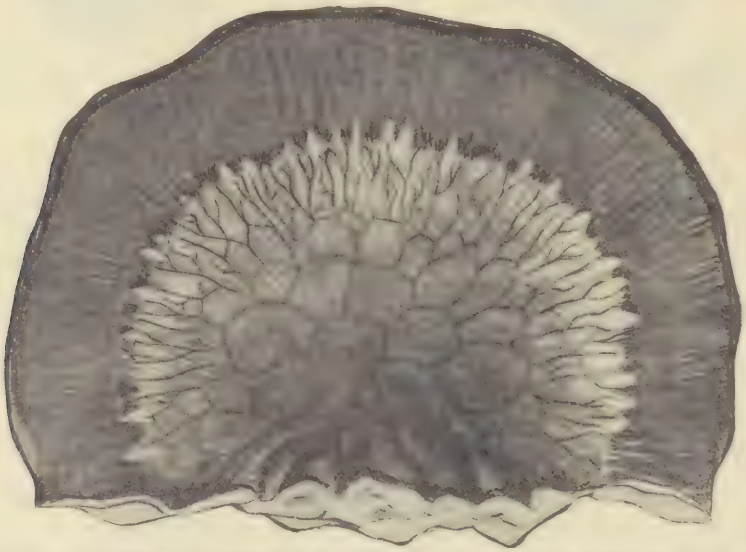

FIG. 873.—A loop of intestine at seventeen feet. The mesentery is opaque, and small tabs of fat begin to appear along the mesenteric border of the gut. The vessels are represented by a somewhat complicated network, and are seen with difficulty in the thick fat of the mesentery. (The specimen came from the subject which furnished Figs. 869, 871, and 872.) (Monks.)

"*The Loops of the Mesenteric Vessels* (Figs. 869, 870, 871, 872, and 873).—Opposite the upper part of the bowel there are only primary loops. Occasionally a secondary loop appears, but it is small and insignificant as compared with the primary loops, which are large and quite regular. As we proceed down the bowel secondary loops become more numerous, larger, and approach

nearer to the bowel than the primary loops in the upper part. As a rule, secondary loops become a prominent feature at about the fourth foot. As we continue farther downward, the secondary loops (and, possibly, tertiary loops) become still more numerous and the primary loops smaller, the loops all the time getting nearer and nearer to the gut. Opposite the lower part of the gut the loops generally lose their characteristic appearance, and are represented by a complicated network.

"*The Vasa Recta.*—Opposite the upper part of the intestine the vasa recta are from three to five centimetres long, when the loop of small intestine to which they run is lifted up so as to put them gently on the stretch. They are straight, large, and regular, and rarely give off branches in the mesentery. In the lower third they are very short, being generally less than one centimetre in length. Here they are less straight, smaller, less regular, and have frequent branches in the mesentery."

FIG. 874.—A loop of intestine at twenty feet. The gut appears to be thick and large. The mesentery is quite fat and opaque, and large and numerous fat-tabs are present. The vessels, which are complicated, are seen with difficulty, and are represented by mere grooves in the fat. (The subject was a stout woman, and the entire length of the gut was twenty-one feet.) (Monks.)

The translucency of the mesentery varies greatly; in some parts it may be almost transparent, in others almost or quite opaque. Its thinnest part is above. It is thickened below by fat, fibrous tissue, and muscular tissue. In very fat subjects it may be impossible to see the vessels (Monks). According to Monks, if a loop is raised and looked at against the light close to the gut "little transparent spaces" are seen between the vasa recta, and even in the thickest mesentery; some of these "lunettes" exist along the upper portion of the intestine. As we descend in our examination, they grow smaller and become fatty, and disappear about the eighth foot of the intestine.[1] The same author shows that the mesentery of the lower third of the intestine, except in the thinnest individuals, contains little collections of fat on the border of the mesentery, which project toward the bowel and may even extend upon it.

THE STOMACH (VENTRICULUS) (Figs. 861, 875, 876, 878, 879).

The stomach is the principal organ of digestion. It is the most dilated part of the alimentary canal, and is situated between the termination of the oesophagus (*cardia*) and the commencement of the small intestine. Its form varies because of varied conditions, but, as a rule, it is somewhat pyriform. It is placed, in part, immediately behind the anterior wall of the abdomen and beneath the Diaphragm. Viewing the stomach from in front it appears that the right margin of the oesophagus is continued downward as the upper two-thirds of the lesser curvature of the stomach, the remaining third of this border bending sharply

[1] Annals of Surgery, October, 1903.

backward and to the right, to complete the smaller curvature (Fig. 875). The greater curvature begins at the left border of the termination of the oesophagus in a somewhat acute angle; it then passes upward and to the left to the under surface of the Diaphragm, with which it lies in contact for some distance, and then sweeps downward with a convexity to the left, and, continued across the middle line of the body, finally turns upward and backward, to terminate at the commencement of the small intestine. It will thus be seen that the stomach may be divided into a **fundus** (*fundus ventriculi*) and a **middle portion** or **body** (*corpus ventriculi*). The portion of the body adjacent to the cardia being known as the **cardiac portion** (*pars cardiaca*), the long axis of which is directed downward with a slight inclination forward and to the right; and the portion adjacent to the pylorus being known as the **pyloric portion** (*pars pylorica*), the long axis of which is horizontal with an inclination backward. Of the two openings, the **cardiac orifice**, by which it communicates with the oesophagus, is situated slightly to the left of the middle line of the body to the right of the fundus, or dilated upper extremity of the stomach, and is directed downward; the other, the **pyloric orifice**, by which it communicates with the small intestine, is on a lower plane, close to the right of the mid-line, and looks directly backward.

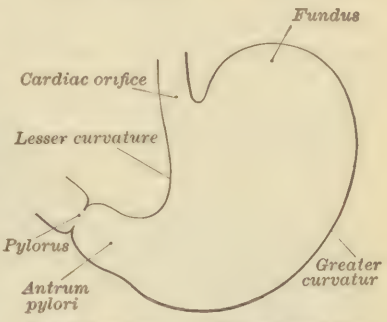

FIG. 875.—Diagrammatic outline of the stomach.

Relations of the Stomach.—The stomach lies in a space or chamber called the **stomach chamber** (Fig. 861). When distended the viscus completely fills the space. When the stomach is empty it lies upon the floor of the chamber, and the portion it has vacated is occupied by the transverse colon, which ascends in front of the stomach and finally gets above it. The **anterior wall** of the stomach chamber is formed by the anterior abdominal wall. The **roof** is formed by the under surface of the Diaphragm and the under surface of the left lobe of the liver. The **floor** is formed by the left suprarenal capsule and the summit of the left kidney, the gastric face of the spleen, the upper surface of the pancreas, the transverse mesocolon, and the colon.[1]

Surfaces.—The stomach has two surfaces, called **anterior** and **posterior surfaces**, and two borders, termed the **greater** and **lesser curvatures.**

In regard to the so-called anterior and posterior surfaces of the stomach, it must be borne in mind that these names are not strictly correct, as the anterior surface has a certain amount of inclination upward and the posterior downward.

The Anterior, Upper or Parietal Surface (*paries anterior*).—The anterior surface is directed forward and to the right side. It has a somewhat flattened appearance when the stomach is empty, but when it is full the surface becomes convex. It is in relation with the Diaphragm; the thoracic wall formed by the anterior parts of the seventh, eighth, and ninth ribs of the left side; the left lobe of the liver; and the anterior abdominal wall. Between the part covered by the liver and that covered by the left ribs there is a triangular segment of the anterior wall of the stomach, which is in contact with the abdominal wall and is the only part of the stomach which is visible when the abdominal wall is removed and the viscera allowed to remain *in situ*. Its area is about 40 sq. cm., and it is of great importance to the surgeon, as the stomach can readily be reached in this situation. Occasionally the transverse colon may be found lying in front of the lower part of the anterior surface of the stomach. The whole of this surface of the stomach is covered by peritoneum.

[1] Prof. Birmingham in Prof. Cunningham's Text-book of Anatomy.

The Posterior, Lower or Visceral Surface (*paries posterior*).—The posterior surface of the stomach is directed backward and to the left. It is in relation with the Diaphragm, the gastric surface of the spleen, the left suprarenal capsule, the upper part of the left kidney, the anterior surface of the pancreas, the splenic flexure of the colon, and the ascending layer of the transverse mesocolon. These structures form a shallow concavity or **bed**, on which this surface of the stomach rests. The transverse mesocolon intervenes between the stomach and the duodenojejunal junction and commencement of the ileum. Its greater curvature is in relation with the transverse colon and has attached to it the anterior two layers of the great omentum. Almost the whole of this surface is covered with peritoneum, but behind the cardiac orifice there is a small portion of the stomach which is uncovered by peritoneum and is in contact with the Diaphragm and frequently with the upper portion of the left suprarenal capsule.

The Lesser Curvature (*curvatura ventriculi minor*).—The lesser curvature of the stomach extends between the cardiac and pyloric orifices along the right border of the organ. It descends in front of the left crus of the Diaphragm, along the left side of the eleventh and twelfth dorsal vertebrae, and then turning to the right it crosses the first lumbar vertebra and ascends to the pylorus. It gives attachment to the two layers of the gastro-hepatic omentum, between which blood-vessels and lymphatics pass to reach the organ.

The Greater Curvature (*curvatura ventriculi major*).—The greater curvature of the stomach is directed to the left, and is four or five times as long as the lesser curvature. Starting from the cardiac orifice, it forms an arch to the left with its convexity upward, the highest point of which is on a level with the costal cartilage of the sixth rib of the left side. It then passes nearly straight downward, with a slight convexity to the left, as low as the costal cartilage of the ninth rib, and then turns to the right to end at the pylorus. As it crosses the median line the lowest edge of the greater curvature is about two fingers' breadth above the umbilicus. The lower part of the greater curvature gives attachment to the two anterior layers of the great omentum, between which layers vessels and lymphatics pass to the organ.

The Cardia (Fig. 876).—The cardia is the point at which the oesophagus enters the stomach wall. The opening is called the **cardiac orifice** or the **oesophageal opening**. At the cardia the circular muscular fibres constitute a sphincter.

The Cardiac Orifice (Fig. 876).—The cardiac orifice is the opening by which the oesophagus communicates with the stomach. It is therefore sometimes termed the **oesophageal opening**. It is the most fixed part of the stomach, and is situated about two inches below the highest part of the fundus on a level with the body of the tenth or eleventh dorsal vertebra to the left and a little in front of the aorta. This would correspond on the anterior surface of the body to the articulation of the seventh left costal cartilage to the sternum. It is placed far off from the surface and is at least four inches back of the seventh left chondro-sternal articulation.

The Pylorus (Fig. 876).—The pylorus is the point at which the stomach passes into the duodenum. The opening of communication is called the **pyloric orifice**. At the pylorus the muscular fibres constitute a sphincter.

The Pyloric Orifice (Fig. 876).—The pyloric orifice communicates with the duodenum, the aperture being guarded by a valve (Fig. 877). Its position varies with the movements of the stomach. When the stomach is empty the pylorus is situated just to the right of the median line of the body, on a level with the upper border of the first lumbar vertebra. On the anterior surface of the body its position would be indicated by a point one inch below the tip of the ensiform cartilage and a little to the right. As the stomach becomes distended the pylorus moves to the right, and in a fully distended stomach may be situated two or three inches to the right of the median line. The direction of the pylorus is upward and to

the right, which position prevents "the weight of the gastric contents bearing directly on the sphincter apparatus."[1] The pylorus is on a somewhat higher level than the lowest point of the stomach. Near the pylorus the stomach frequently exhibits a slight dilatation, which is named the **antrum of the pylorus** (*antrum pyloricum*). The pylorus is indicated by a constriction, the direction of which is circular. The pylorus lies upon the neck of the pancreas behind. Above it and in front of it is the liver.

The size of the stomach varies considerably in different subjects. When moderately distended its greatest length, from the top of the fundus to the lowest part of the greater curvature, is from ten to twelve inches and its diameter at the widest part from four to five inches. The distance between the two orifices is three to six inches, and the measurement from the anterior to the posterior wall three and a half inches. Its weight, according to Clendinning, is about four ounces and a half, and its capacity in the adult male is five to eight pints. The stomach of a newborn child holds about one ounce.

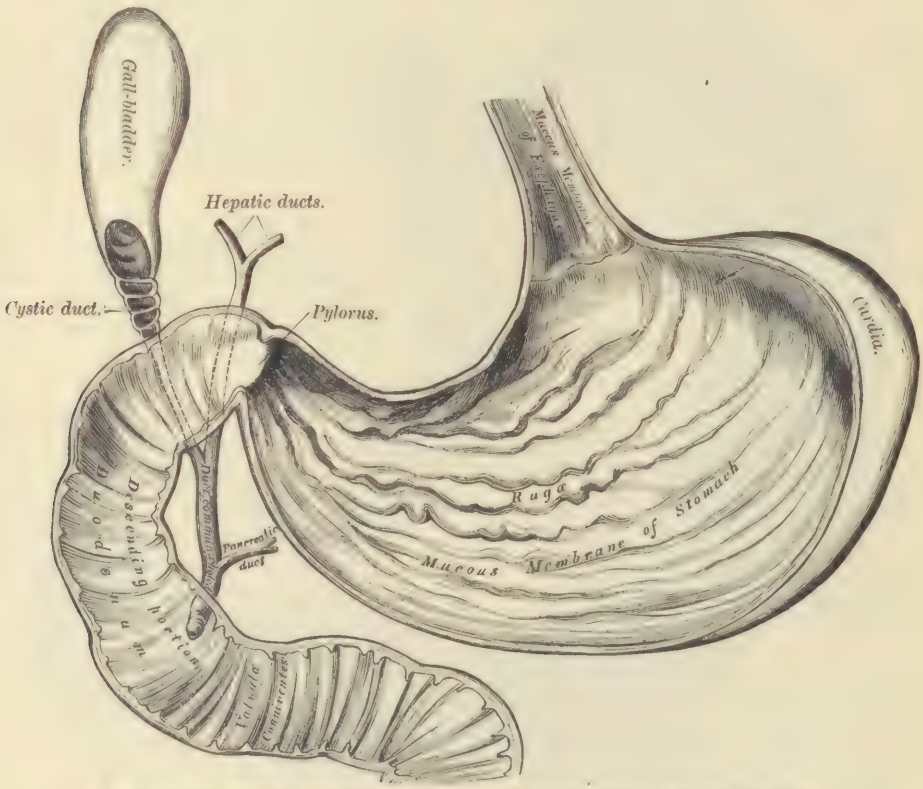

FIG. 876. The mucous membrane of the stomach and duodenum with the bile-ducts.

Alterations in Position. —There is no organ in the body the position and connections of which present such frequent alterations as the stomach. *When empty*, it lies at the back part of the abdomen, some distance from the surface, and is in the left hypochondriac region and the left portion of the epigastric region. Its fundus is directed upward and backward toward the Diaphragm. The long axis of the viscus is nearly horizontal. Its pyloric end is directed upward and backward, is situated close to or very slightly to the right of the middle line, covered in front by the left lobe of the liver, and being on a level with the first lumbar vertebra. When empty, the stomach assumes a more or less cylindrical form, especially noticeable at its pyloric end. The entire viscus is small and contracted, and the pyloric region resembles the intestine. *When the stomach is distended*, its surfaces, which are flattened when the organ is empty, become convex and the shape becomes pyriform. The viscus becomes very oblique and approaches the vertical,

[1] W. J. Mayo, Medical Record, June 11, 1904.

its long axis being downward, forward, and to the right. The greater curvature is elevated and carried forward, so that the anterior surface is turned more or less upward and the posterior surface downward, and the stomach is brought well against the anterior wall of the abdomen. Its fundus expands and rises considerably above the level of the cardiac orifice; in doing this the Diaphragm is forced upward, contracting the cavity of the chest; hence the dyspnœa complained of, from inspiration being impeded. The apex of the heart is also tilted upward; hence the oppression in this region and the palpitation experienced in extreme distention of the stomach. The left lobe of the liver is pushed to the right side. When the stomach becomes distended the change in the position of the pylorus is very considerable; it is shifted to the right, some two or three inches from the median line, and lies under cover of the liver, near the neck of the gall-bladder. In consequence of the distention of the stomach the lesser *cul-de-sac* bulges over the pylorus, concealing it from view, and causing it to undergo a rotation, so that its orifice is directed backward. When the stomach is greatly distended its lower border may enter the umbilical and the left lumbar regions. *During inspiration* the stomach is displaced downward by the descent of the Diaphragm, and it is elevated by the pressure of the abdominal muscles during *expiration*. *Pressure from without*, as from tight lacing, pushes the stomach down toward the pelvis. In fact, in the female, because of tight lacing, the stomach may be to the left side of the vertebral column and nearly vertical in direction, the lower portion being sharply angled upward toward the pylorus, which lies underneath the liver. Besides the angulation, the lower end, the stomach may have a median constriction, and there may even be an hour-glass stomach. The descent of the stomach from tight lacing may cause the pancreas to become nearly vertical. In disease the position and connection of the stomach may be greatly changed, from the accumulation of fluid in the chest or abdomen, or from alteration in size of any of the surrounding viscera.

Variations according to Age.—In an early period of development the stomach is vertical, and in the newborn child it is more vertical than later on in life, as owing to the large size of the liver it is more pushed over to the left side of the abdomen, and the whole of the anterior surface is covered by the left lobe of this organ.

On looking into the pyloric end of the stomach, the mucous membrane is found projecting inward in the form of a circular fold, the **pyloric valve** (Fig. 877), leaving a narrow circular aperture, about half an inch in diameter, by which the stomach communicates with the duodenum.

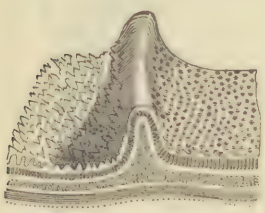

Fig. 877.—Diagrammatic view of the coats of the stomach, duodenum, and pylorus. The ridge is the pyloric valve. (Allan Thomson.)

The Pyloric Valve (*valvula pylori*) (Fig. 877).—The pyloric valve is formed by a reduplication of the mucous membrane of the stomach, containing numerous circular fibres, which are aggregated into a thick circular ring, the **pyloric sphincter** (*m. sphincter pylori*); the longitudinal fibres and serous membrane being continued over the fold without assisting in its formation (Fig. 877). The pylorus is normally kept closed by the action of this aggregation of circular fibres which constitutes the Sphincter muscle. During the early stage of digestion it remains closed, but after a time opens now and then. The opening becomes more frequent and the period of patency is prolonged as digestion advances.

The diameter of the pylorus is uncertain. It is usually said to be half an inch. But it is closed when the pylorus is at rest, and it can certainly dilate even in a child to at least an inch and let bodies of this size pass through.

The Peritoneum.—The **great omentum** comes off from the greater curvature of the stomach and passes to the transverse colon. The **lesser omentum** comes off from the lesser curvature and passes to the liver. The **gastro-splenic ligament** or **omentum** passes from the under surface of the stomach just below the greater curvature to the spleen. A fold of peritoneum passes up from the stomach along the left side of the oesophagus to the Diaphragm. This is the **gastro-phrenic ligament.**

Supports of the Stomach.—The stomach lies on the bed of the stomach chamber, which was described on p. 1269. The great omentum gives no support to the stomach, neither does the gastro-splenic ligament, because of the movability of the spleen. The **lesser omentum** does give support to the stomach and so do

the **gastro-phrenic ligament** and the **hepato-duodenal ligament.** The two chief points of support are the attachment of the oesophagus to the Diaphragm and the fixation of the duodenum to the front of the vertebral column.

Structure.—The wall of the stomach consists of four coats: **serous, muscular, areolar,** and **mucous,** together with vessels and nerves.

The Peritoneal or Serous Coat (*tunica serosa*).—The peritoneal or serous coat covers the entire surface of the organ, excepting along the greater and lesser curvatures, at the points of attachment of the greater and lesser omenta; at each curvature the two layers of peritoneum leave a small triangular space, to which the peritoneum is not attached, although it is attached in front of it and back of it. Along these spaces the nutrient vessels and nerves pass. On the posterior surface of the stomach, close to the cardiac orifice and below and to the left of it, there is a smaller triangular area uncovered by peritoneum, where the organ is in contact with the under surface of the Diaphragm, and it may be

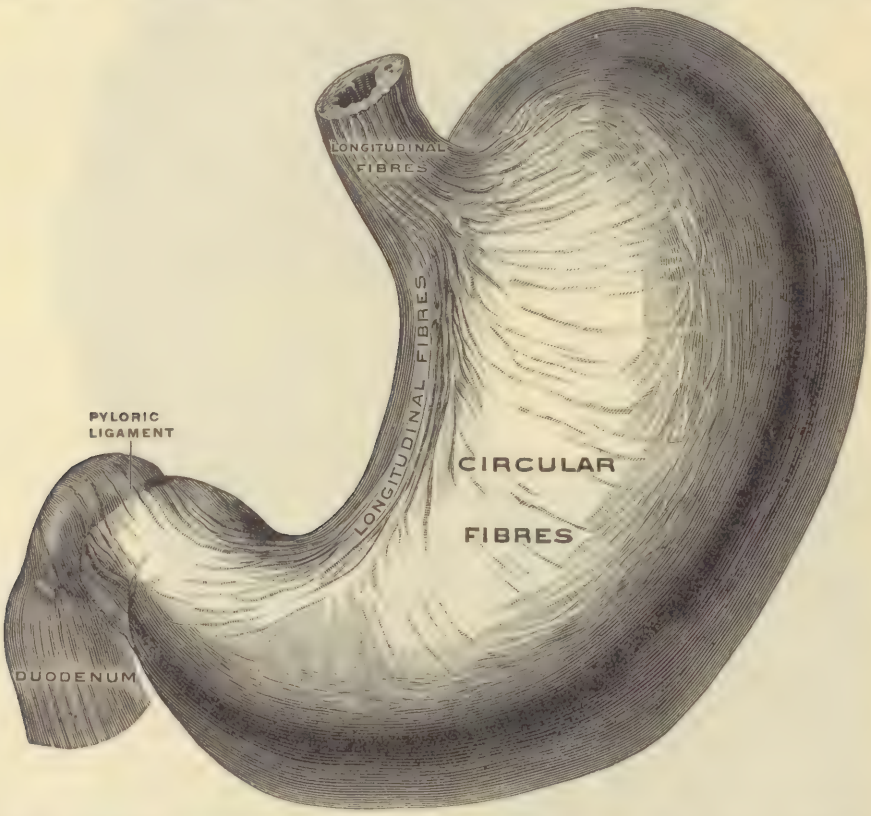

FIG. 878.—The superficial muscular layer of the stomach, viewed from above and in front. (Spalteholz.)

with the left suprarenal body and the summit of the left kidney. When the stomach is moderately distended this **uncovered area** measures about one and a half inches from above downward, and about two inches from before backward. At the left angle of this uncovered area the insertion of the great omentum begins. At the right angle the gastric artery reaches the stomach.

The Muscular Coat (*tunica muscularis*) (Figs. 878 and 879).—The muscular coat is situated immediately beneath the serous covering, to which it is closely connected. It consists of three sets of fibres—**longitudinal, circular,** and **oblique.**

The **Longitudinal Fibres** (*stratum longitudinale*) are most superficial; they are continuous with the longitudinal fibres of the oesophagus, radiating in a stellate

manner from the cardiac orifice. They are most distinct along the curvatures, especially the lesser, but are very thinly distributed over the surfaces. At the pyloric end they are more thickly distributed, and continuous with the longitudinal fibres of the small intestine. The bundles of longitudinal muscle-fibre on the upper and lower surfaces of the pylorus are particularly firm and distinct, and are called the **pyloric ligaments** (*ligamenta pylori*).

The **Circular Fibres** (*stratum circulare*) form a uniform layer over the whole extent of the stomach, except the fundus, beneath the longitudinal fibres. At the pylorus they are most abundant, and are aggregated into a circular ring or **sphincter** (*m. sphincter pylori*), which projects into the cavity, and forms, with the fold of mucous membrane covering its surface, the **pyloric valve** (*valvula pylori*) (Fig. 877). They are continuous with the circular fibres of the oesophagus.

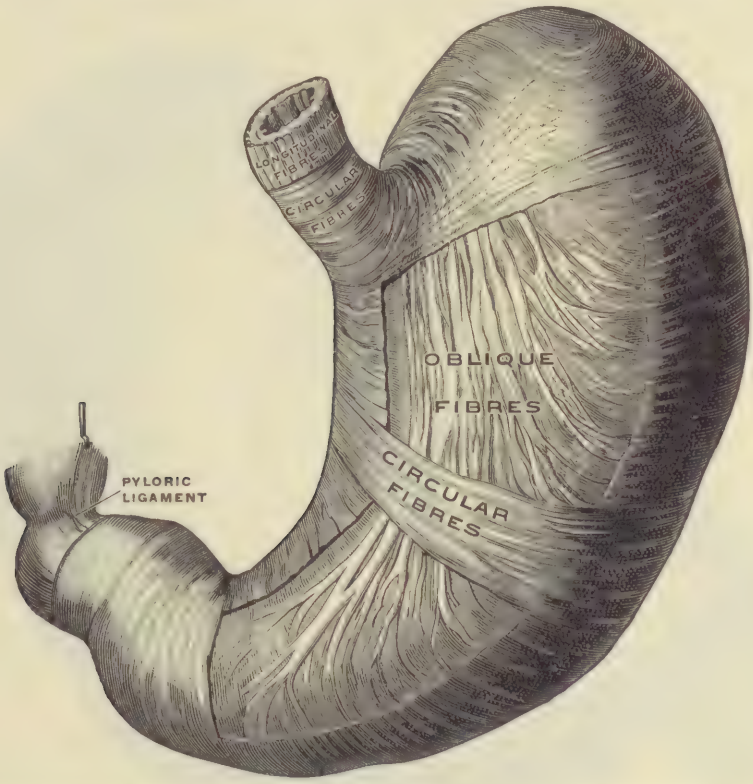

FIG. 879.—The middle and deep muscular layer of the stomach, viewed from above and in front. (Spalteholz.)

The **Oblique Fibres** (*fibrae obliquae*) arise at the left side of the cardia from the circular fibres of the oesophagus. The fibres pass down in the anterior and posterior walls. Those of the anterior wall are parallel to the lesser curvature and almost reach the pylorus. Those of the posterior wall are more nearly transverse to the long axis of the stomach (Spalteholz). These fibres gradually assume the direction of the circular fibres and terminate in them. The layer of oblique fibres is beneath the circular layer. Certain oblique muscular fibres encircle the fundus of the stomach in a series of rings.

The Areolar or Submucous Coat (*tela submucosa*).—The areolar or submucous coat consists of loose, filamentous, areolar tissue, connecting the mucous and muscular layers. It supports the blood-vessels previous to their distribution to the mucous membrane; hence it is sometimes called the **vascular coat.**

The Mucous Membrane (*tunica mucosa*) (Figs. 880, 881, and 882).—The mucous membrane is thick; its surface smooth, soft, and velvety. In the fresh state it is of a pinkish tinge at the pyloric end, and of a red or reddish-brown

Fig. 880. Mucous membrane of the stomach, from the pars pylorica, viewed from the surface. × 5. (Spalteholz.)

color over the rest of the surface. In infancy it is of a brighter hue, the vascular redness being more marked. It is thin at the cardiac extremity, but thicker toward the pylorus. During the contracted state of the organ it is thrown into numerous plaits or **rugae** (*plicae mucosae*) (Figs. 880 and 882 *A*), which for the most part have a longitudinal direction, and are most marked toward the lesser end of the stomach and along the greater curvature, and which contain also submucous tissue. These folds are entirely obliterated when the organ becomes distended. A constant fold exists at the pylorus (Fig. 877). It is called the **pyloric valve**, and is produced by the presence beneath it of the Sphincter muscle.

Besides the large folds or rugae and the pyloric valve, there are numerous small elevations of mucous membrane known as **gastric areas** (*areae gastricae*), which are partly separated from each other by furrows and which vary greatly in shape (Fig. 880). According to Spalteholz, each one of these elevations has an area of several square millimetres.

Fig. 881.—Mucous membrane of the stomach, from the pars pylorica, viewed from the surface. ×16. (Spalteholz.)

Structure of the Mucous Membrane.—When examined with a lens the inner surface of the mucous membrane presents a peculiar honeycomb appear-

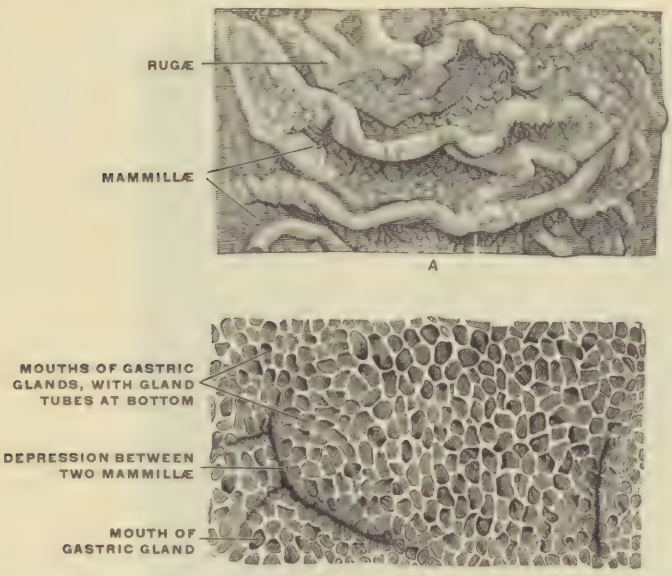

Fig. 882.—The mucous membrane of the stomach. *A*, natural size; *B*, magnified 25 diameters. In *A* the rugæ and the mammillated surface are shown. In *B* the gland mouths (foveolæ gastricæ), with the gland tubes leading from some of them, and the ridges separating the mouths (plica villosæ) are seen. (Cunningham.)

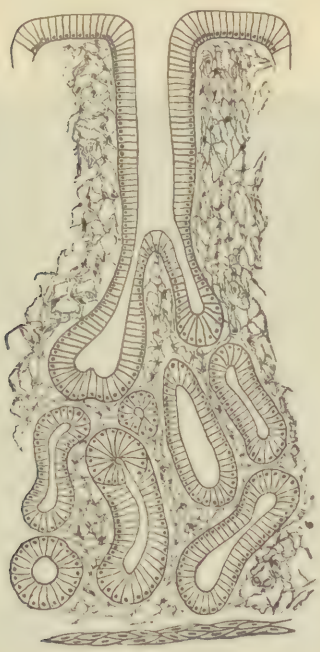

Fig. 883.—Pyloric gland.

Fig. 884.—Peptic gastric gland

ance, from being covered with small shallow depressions or **alveoli** (*foveolæ gastricæ*) (Figs. 881 and 882, *B*) of a polygonal or hexagonal form, which vary

from $\frac{1}{100}$ to $\frac{1}{200}$ of an inch in diameter, and are separated by slightly elevated ridges (*plicae villosae*). The ridges are most distinct at the pylorus. These foveolae are within the areae gastricae. The ridges on section resemble villi. In the bottom of the alveola are seen the orifices of minute tubes, the **gastric glands** (Fig. 882 *B*), which are placed perpendicularly side by side throughout the entire substance of the mucous membrane. The surface of the mucous membrane of the stomach is covered by a single layer of **columnar epithelium**; it lines the alveoli, and also for a certain distance the mouths of the gastric glands. This epithelium commences very abruptly at the cardiac orifice, where the cells suddenly change in character from the **stratified epithelium** of the oesophagus. The cells are elongated, and consist of two parts, the inner or attached portions being granular, and the outer or free parts being clear and occupied by a mucoalbuminous substance.

The Gastric Glands.—The gastric glands are of three kinds: the **true gastric glands**, the **pyloric glands**, and the **cardiac glands**.

The **True Gastric Glands** (Fig. 884) are called also the **oxyntic glands**, the **fundus glands**, and the **peptic glands** (*glandulae gastricae propriae*). They are distributed throughout the entire fundus and body, and may be found even at the pylorus. They are tubular in character, and are formed of a delicate basement-membrane, lined with epithelium. The basement-membrane consists of flattened transparent endothelial cells, with processes which extend between and support the epithelium. Into the crypt of a true gastric gland three or more caecal tubes, branched or unbranched, empty. The duct, however, in these glands is shorter than in the other variety, sometimes not amounting to more than one-sixth of the whole length of the gland; it is lined throughout by columnar epithelium. At the point where the terminal tubes open into the duct, and which is termed the **neck**, the epithelium alters, and consists of short columnar or polyhedral, granular cells, which almost fill the tube, so that the lumen becomes suddenly constricted, and is continued down as a very fine channel. They are known as the **chief** or the **peptic** or the **central cells of the glands**, and furnish pepsin. Between these cells and the basement-membrane are found other darker granular-looking cells, studded throughout the tubes at intervals, and giving it a beaded or varicose appearance. These are known as the **parietal** or **oxyntic cells**. Some of the parietal cells empty directly into the lumen of the gland by secretory capillaries; others empty by a duct which divides into secretory capillaries. The parietal cells secrete the acid of the gastric juice. Between the glands the mucous membrane consists of a connective-tissue framework with lymphoid tissue. In places this latter tissue, especially in early life, is collected into little masses, which to a certain extent resemble the solitary glands of the intestine, and are by some termed the **lenticular glands of the stomach**. They are not, however, so distinctly circumscribed as the solitary glands.

The **Pyloric Glands** (*glandulae pyloricae*) (Fig. 883) are the branched tubular glands, and secrete mucus.

They are placed most plentifully about the pylorus, but between the fundus and pylorus, in the region known as the **transitional** or **intermediate zone**, both true gastric glands and pyloric glands are found. Each pyloric gland consists of two or three short, closed tubes opening into a common duct, the external orifice of which is situated at the bottom of an alveolus. The caecal tubes are wavy, and are of about equal length with the duct. The tubes and duct are lined throughout with epithelium, the duct being lined by columnar cells continuous with the epithelium lining the surface of the mucous membrane of the stomach, the tubes with shorter and more cubical cells, which are finely granular. The pyloric glands branch more frequently, are more curved in direction, and open into deeper foveolae than the true gastric glands (Szymonowicz). They contain only chief or peptic cells and do not possess parietal cells.

The **Cardiac Glands** are found about the oesophageal orifice. They resemble the pyloric glands.

Beneath the mucous membrane, and between it and the submucous coat, is a thin stratum of involuntary muscular fibre (*muscularis mucosae*), which in some parts consists only of a single longitudinal layer; in others, of two layers, an inner circular, and an outer longitudinal.

Vessels and Nerves.—The **arteries** supplying the stomach are—the **gastric** or **coronary**, the **pyloric** and the **right gastro-epiploic branch of the gastro-duodendal**, the **left gastro-epiploic** and **vasa brevia** from the splenic. The gastric artery passes to the lesser curvature just below the cardia. It gives off the **oesophageal branch**, and passes from left to right along the lesser curvature of the stomach beneath the peritoneum between the two layers of the lesser omentum and upon the wall of the stomach. It may in this course be a single vessel, or may divide into two branches, which run along each side of the lesser curvature (Fig. 886). If there is a single artery it gives off six or seven descending branches to the anterior wall and about the same number to the posterior wall of the stomach. It also gives branches to the lesser omentum. If two **vascular arches** form, one gives branches to the anterior wall of the stomach, the other to the posterior wall, and both to the lesser omentum. The termination of the gastric anastomoses with the pyloric branch or two rami of the pyloric branch of the hepatic artery. From each arch six or seven **descending branches** come off to the anterior and posterior

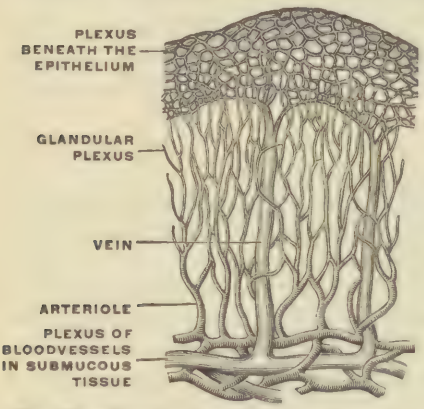

Fig. 885.—Terminations of the blood-vessels in the mucous membrane of the stomach. (Poirier and Charpy.)

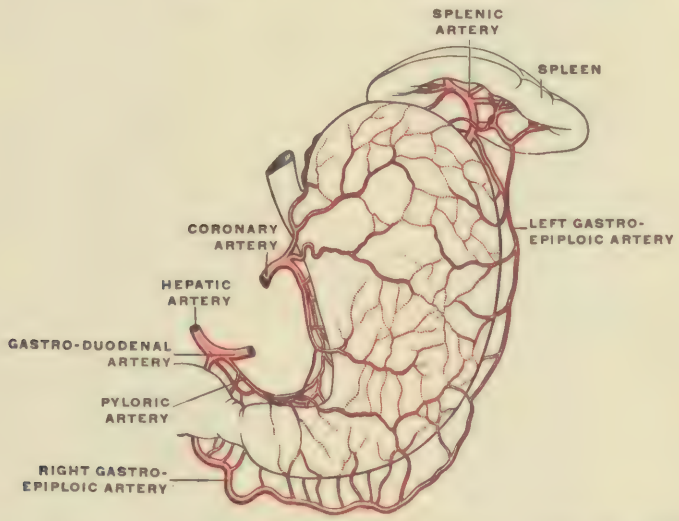

Fig. 886.—The arteries of the anterior surface of the stomach. (Poirier and Charpy.)

walls of the stomach. The **gastro-duodenal artery** is given off by the hepatic. From the gastro-duodenal comes the right gastro-epiploic. The left gastro-epiploic comes from the splenic. The **right gastro-epiploic artery** passes from right to left in the gastro-colic omentum below the greater curvature of the

stomach. The **left gastro-epiploic artery** passes forward in the gastro-splenic ligament to below the greater curvature of the stomach, and passes from left to right along that curvature in the gastro-colic omentum, and joins the right gastro-epiploic artery. The gastro-epiploic arteries are not upon but are distinctly below the stomach wall. From them numerous gastric branches are sent to the anterior and posterior walls of the stomach, and they anastomose with branches of the gastric and pyloric. Vasa brevia, four or five in number, arise from the splenic, pass forward in the gastro-splenic ligament, and supply the fundus. The arteries of the stomach lie first beneath the peritoneum, but soon enter the muscular coat, supply it, pierce it, ramify in the submucous coat, and are finally distributed to the mucous membrane. The arrangement of the vessels in the mucous membrane is somewhat peculiar (Fig. 885). The arteries break up at the base of the gastric tubules into a plexus of fine capillaries which run upward between the tubules, anastomosing with each other, and ending in a plexus of larger capillaries, which surround the mouths of the tubes and also form hexagonal meshes around the alveoli.

The capillary networks about the glands give origin to the **veins**. The various small **veins unite and form a plexus in the submucous tissue** (Fig. 885). From this plexus come branches which pass through the muscular coat and terminate in the **right gastro-epiploic branch of the superior mesenteric**, the **left gastro-epiploic branch of the splenic**, the veins to the splenic which correspond to the **vasa brevia arteries**, and the **gastric** or **coronary branch of the portal**.

The **lymphatics** (Figs. 507 and 508) arise in the mucous membrane and terminate in a network in the submucous tissue. From this network trunks arise which perforate the muscular coat in the regions of the curvatures and terminate in the sero-muscular collecting trunks.[1]

According to Cunéo, there are three groups of these collectors. Those from the lesser curvature pass to the point where the gastric artery reaches the stomach and enter the **glands along the gastric artery**. Those from the greater curvature pass from left to right and enter the **sub-pyloric glands**. Those from the fundus pass from right to left and end in the **splenic glands**. Cunéo further pointed out that the region drained by the collectors of the lesser curvature is divided from the others by the line shown in Fig. 507. This division exists on both surfaces of the stomach. The limit between the collectors which drain into the splenic glands and those which drain into the sub-pyloric glands is also shown in Fig. 507. Along the lesser curvature the lymph-glands are few in number and are limited to the pyloric region, and the lymph-vessels are placed directly upon the stomach wall. The lymph-glands and vessels are not upon but are *distinctly below* the greater curvature.

The subserous and submucous lymphatic networks of the stomach communicate with the corresponding networks of the oesophagus, but in all probability do not communicate with the networks of the duodenum.

The **nerves of the stomach** come from the **right** and **left pneumogastrics** and from the **solar plexus of the sympathetic**. The left pneumogastric passes to the front of the stomach, and the right nerve passes to the back, and they unite with the fibres of the sympathetic. The fibres thus formed are mostly non-medullated. They form **Auerbach's plexus** in the muscular coat between the circular and longitudinal fibres and **Meissner's plexus** in the submucous coat, the latter plexus being formed by fibres from the former. Fibres from Meissner's plexus ramify in the submucous coat and terminate in the muscularis mucosae and the mucous membrane, branches passing to the gastric glands and to just beneath the epithelium.

[1] The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.

Movements and Innervation of the Stomach.

Movements.—It has apparently been demonstrated that the stomach "consists of two parts physiologically distinct."[1] The cardiac portion of the stomach is a food reservoir in which salivary digestion continues; the pyloric portion is the seat of active digestion. Cannon affirms that there are no peristaltic waves in the cardiac portion, but that as the food passes from the pyloric portion into the intestines, tonic contraction of the muscles of the fundus squeezes the contents of the pyloric portion. Moritz, Levan, and Cannon assert that muscular activity is chiefly manifested in the pyloric portion. In this portion during digestion there is a succession of peristaltic waves, which waves in the human being pass at the rate of three per minute (Moritz). Cannon points out that the efficiency of peristalsis in mixing the food depends upon the contraction of the pyloric sphincter. So long as the sphincter holds, each constriction-ring coursing from the middle to the end of the stomach presses the food into a blind pouch; the food, unable to escape through the pyloric opening, has as its only outlet the opening in the advancing ring. This is an admirable device for bringing the food under the influence of the glandular secretions of the pyloric region. For, as a constriction occurs, the secreting surface enclosed by the narrowed muscular ring is pressed close around the food within the ring. As the constriction advances it continually presses inward fresh glandular tissue, and furthermore, as the constriction advances, a thin stream of food is continuously forced back through the ring and thus past the mouths of the glands. The old view that the pyloric sphincter only opens after several hours' continuance of the process of digestion and that then the stomach empties at once is incorrect. It is emptied in small amounts which escape at frequent intervals because of the intermittent opening of the pylorus. When the pylorus is open a wave of peristalsis forces some of the material from the stomach into the duodenum (Cannon).

Cannon is of the opinion that the pyloric sphincter is caused to relax by the presence of free hydrochloric acid in the pyloric portion of the stomach. When the pylorus is open acid chyme passes into the duodenum and acid in the duodenum causes the pylorus to close. The acid in the duodenum causes a flow of alkaline pancreatic juice and the acid is neutralized. "As the neutralizing proceeds the stimulus closing the pylorus is weakened until the acid in the stomach again opens the sphincter."[2]

Innervation.—The stomach, as previously shown, has nervous plexuses in its walls and is connected to the brain, spinal cord, and sympathetic system. It is probable that gastric peristalsis is due to a local reflex from Auerbach's plexus (Magnus), the local reflex being inaugurated by local stimulation, which stimulation, in the words of Bayliss and Starling, "produces excitation above and inhibition below the excited spot."[3] Reversed peristalsis cannot occur if "the reflex mechanism is intact" (Cannon). Cannon in the previously quoted article states that cutting the vagus or splanchnic nerves does not destroy the reflex mechanism of the pylorus, but, nevertheless, it is markedly affected by the central nervous system.

Surface Form (see p. 1271).—The cardiac orifice corresponds to the articulation of the seventh left costal cartilage with the sternum. The pyloric orifice of the empty stomach is in a vertical line drawn from the right border of the sternum, two and a half or three inches below the level of the sterno-xiphoid articulation. According to Braune, when the stomach is distended, the pylorus moves considerably to the right, as much sometimes as three inches. The fundus of the stomach reaches, on the left side, as high as the level of the sixth costal cartilage of the left side, being a little below and behind the apex of the heart. The portion of the distended stomach which is in contact with the abdominal walls, and is therefore accessible for opening in the operations of gastrotomy and gastrostomy, is represented by a triangular space, the base of which is formed by a line drawn from the tip of the tenth costal cartilage on the left side to the tip of the ninth costal cartilage on the right, and the sides by two lines drawn from the extremity of the eighth costal cartilage on the left side to the ends of the base line.

Surgical Anatomy.—Operations on the stomach are frequently performed, ulcers are excised, malignant growths are removed with the associated lymphatic involvement, the entire stomach may be removed for cancer, etc. By "*gastrotomy*" is meant an incision into the stomach for the removal of a foreign body, or the arrest of hemorrhage or for exploration, the opening being immediately afterward closed—in contradistinction to "*gastrostomy*," the making of a more or less permanent fistulous opening. *Gastrotomy* is probably best performed by an incision in the linea alba, especially if the foreign body is large. The cut may reach from the ensiform cartilage to the umbilicus. The incision may be made over the body itself, where this can be felt, or by one of the incisions for gastrostomy, to be mentioned shortly. The peritoneal cavity is opened, and the point at which the stomach is to be incised decided upon. This portion is then brought out of the abdominal wound and sponges carefully packed around. The stomach is now opened by a transverse incision and the foreign body extracted. The wound in the stomach is then closed by Lembert sutures—*i. e.*, by sutures passed through the peritoneal,

[1] Walter B. Cannon, Medical News, May 20, 1905. [2] Ibid. [3] Ibid.

muscular and submucous coats in such a way that the peritoneal surfaces on each side of the wound are brought into apposition. *Gastrostomy* was formerly done in two stages by the *direct* method. The first stage consisted in opening the abdomen, drawing up the stomach into the external wound, and fixing it there; and the second stage, performed from two to four days afterward, consisted in opening the stomach. The operation is now done by a *valvular* method. The following plan is known as the Ssabanejew-Frank operation. An incision is commenced opposite the eighth intercostal space, two inches to the left of the median line, and carried downward for three inches. By this incision the fibres of the Rectus muscle are exposed and these are separated from each other in the same line. The posterior layer of the sheath, the transversalis fascia and the peritoneum, are then divided, and the peritoneal cavity is opened. Instead of the above incision, the curved incision of Fenger can be made at the margin of the left costal cartilages. The anterior wall of the stomach is now seized and drawn out of the wound and a silk suture passed through its submucous, muscular, and serous coats at the point selected for opening the viscus. This is held by an assistant so that a long conical diverticulum of the stomach protrudes from the external wound, and the parietal peritoneum and the posterior layer of the sheath of the rectus are sutured to the base of the cone. A second incision is made through the skin, over the margin of the costal cartilage, *above and a little to the outer side* of the first incision. If Fenger's incision were used, the second incision should be above the margin of the cartilages. With a pair of dressing forceps a track is made under the skin through the subcutaneous tissue from the one opening to the other and the diverticulum of the stomach is drawn along this track by means of the suture inserted into it; so that its apex appears at the second opening. A small perforation is now made into the stomach through this protruding apex and its margin carefully and accurately sutured to the margin of the external wound. The remainder of this incision and the whole of the first incision are then closed in the ordinary way and the wound dressed.

In cases of *gastric ulcer*, *perforation* sometimes takes place, and this was formerly regarded as an almost fatal complication. In the present day, by opening the abdomen and closing the perforation, which is generally situated on the anterior surface of the stomach, a considerable percentage of cases are cured, provided the operation is undertaken within twelve to fifteen hours after the perforation has taken place. The opening is best closed by bringing the peritoneal surfaces on either side into apposition by means of Lembert sutures.

Pylorectomy or excision of the pylorus is performed, particularly for early cancer, but is also done for cicatricial stricture and for ulcer. The mortality after operation for cancer was, until recently, very great, but of late years it has been notably reduced, though it is still much higher than that which follows operation for any non-malignant condition.

In operating for cancer, bear in mind Cunéo's study of the lymphatics (page 806). These observations indicate that the fundus and two-thirds of the greater curvature are free from lymphatic involvement in pyloric cancer.[1] In every operable case of cancer of the pylorus the entire lesser curvature must be removed up to the gastric artery (Mikulicz's point), and the greater curvature must be removed to the left of the involved glands (Hartmann's rule).

Gastro-enterostomy is an operation which establishes a fistulous communication between the stomach and jejunum. The operation is often called *gastro-jejunostomy*. The opening may be made upon either the anterior or the posterior wall of the stomach, between the cardia and the seat of pyloric disease. The operation is employed for stricture of the pylorus (benign or malignant), and occasionally for ulcer of the stomach.

Loreta's operation is digital divulsion of the pylorus for cicatricial stricture, the stomach being incised transversely near the pylorus to admit the finger, and the wound in the stomach being sutured after division has been effected. The operation has been abandoned, because contraction recurs.

Pyloroplasty, or the Heineke-Mikulicz operation, displaced Loreta's operation. In this procedure an incision is made through the stricture in the direction of the long axis of the stomach and bowel. By making traction on each side of the incision, the longitudinal wound assumes a vertical direction, and sutures are inserted so as to close the wound in a vertical line. The method of pyloroplasty devised by Finney, of Baltimore, makes a large permanent opening at the most dependent part of the stomach, and is the most satisfactory method of which we are possessed.[2]

Total gastrectomy is the removal of the entire stomach. It is only used for cancer. It was first performed by Conner, of Cincinnati. The first successful operation was done by Schlatter, of Zurich, in 1898. A number of successes have been reported. It is a justifiable operation only in a case in which almost the entire stomach is cancerous, in which the viscus is movable, in which there are no secondary deposits, and no irremovable diseased glands.

Gastro-gastrostomy is an operation employed in hour-glass stomach. In this operation an anastomosis is made between the pyloric and cardiac ends of the stomach.

[1] William J. Mayo, Annals of Surgery, March, 1904.
[2] Johns Hopkins Hospital Bulletin, July, 1902.

Gastroplication is the operation of suturing the stomach wall into folds or reefs, in order to lessen its size. It is employed in some cases of gastric dilatation.

Gastroptosis is a condition in which the stomach is displaced downward. In some of these cases the greater curvature almost reaches the level of the symphysis pubis, and the lesser curvature is midway between the umbilicus and ensiform cartilage. The condition is usually associated with *enteroptosis* and *movable kidney* (nephroptosis). In this condition the gastro-hepatic omentum and the gastro-phrenic ligament are pulled upon and lengthened. The best operation for gastroptosis was devised by Beyea. He applies sutures so as to make folds in and thus shorten the stretched ligament and omentum. Thus the stomach is elevated to its proper position, and its mobility is not lessened, as it is in other operations which suture it to the abdominal wall.

THE SMALL INTESTINE (INTESTINUM TENUE).

The small intestine is a convoluted tube, extending from the pylorus to the ileo-caecal valve, where it terminates in the large intestine. It fills up the greater part of the abdominal cavity and of the pelvic cavity. It is about twenty feet in length,[1] and gradually diminishes in size from its commencement to its termination. The diameter of the duodenum is almost two inches; the diameter of the lower portion of the small intestine is little more than one inch. It is contained in the central and lower part of the abdominal cavity, and is surrounded above and at the sides by the large intestine; a portion of it extends below the brim of the pelvis and lies in front of the rectum; it is in relation, in front, with the great omentum and abdominal parietes; and connected to the spine by a fold of peritoneum, the **mesentery** (p. 1257). The small intestine is divisible into three portions —the **duodenum**, the **jejunum**, and **ileum**.

The Duodenum (Figs. 887, 892, 893, 894, 895).

The duodenum has received its name from being about equal in length to the breadth of twelve fingers (ten inches). It is the shortest, the widest, and the most fixed part of the small intestine, being closely and firmly attached to the posterior abdominal wall. It does not possess a mesentery. Somewhat more than the upper half of the duodenum is placed in the epigastric region; the remainder is in the umbilical region. The duodenum, with the exception of the ascending portion, is to the right of the median line. Its course presents a remarkable curve, which in the adult, as regards the greater part of its extent, is horseshoe-shaped, though sometimes, in consequence of the transverse portion being very short or altogether wanting, it partakes more of the character of the letter V. The opening of the horseshoe being directed upward and to the left. In children up to the age of about seven the duodenum is annular. The two extremities of the duodenum are nearly on the same level, the exit being slightly lower than the entrance. The two ends are about two inches apart; and between them it describes a regular curve embracing the head of the pancreas, the neck of which lies between the two extremities of the ring.

In the adult the course of the duodenum is as follows: commencing at the pylorus the direction of the first portion depends upon the amount of distention of the stomach and therefore upon the position of the pylorus. When the stomach is empty and the pylorus is situated at the right of the upper border of the first lumbar vertebra, it is nearly horizontal and transverse; but where the stomach is distended, in consequence of the alteration of the position of the pylorus to the right the proximal end of the duodenum also becomes altered in position, while the

[1] Treves states that in one hundred cases the average length of the small intestine in the adult male was 22 feet 6 inches, and in the adult female 23 feet 4 inches; but that it varies very much, the extremes in the male being 31 feet 10 inches in one case and 15 feet 6 inches in another, a difference of over 15 feet. He states that he has convinced himself that the length of the bowel is independent, in the adult, of age, height, and weight.—Ed. of 15th English edition.

distal end remains fixed and the direction of this portion of the bowel is now antero-posterior. Whether directed transversely or antero-posteriorly, it reaches

the under surface of the liver, where it takes a sharp curve and descends along the right side of the vertebral column, for a variable distance, generally to the body of

[1] In the subject from which the cast was taken the left kidney was lower than normal.

the fourth lumbar vertebra. It now takes a second bend, and passes across the front of the vertebral column from right to left and finally ascends on the left side of the vertebral column and aorta to the level of the upper border of the second lumbar vertebra and there terminates in the jejunum. As it unites with the jejunum it often turns abruptly forward, forming the **duodeno-jejunal angle**. Prof.

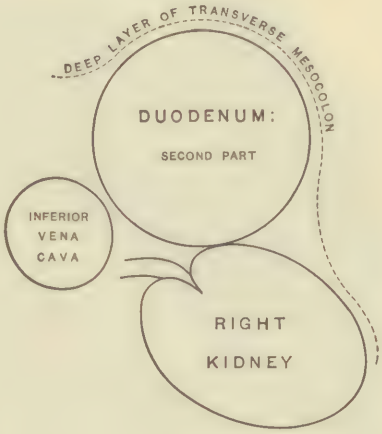

FIG. 889.—Diagram of cross-section of the second part of the duodenum, to show its peritoneal relations. (Gerrish.)

Birmingham points out that the incomplete ring formed by the duodenum does not lie throughout in the same plane. "Its greater part is placed in a transverse vertical plane; the middle portion bends strongly backward, around the right side of the vena cava, and lies almost in a sagittal plane."[1] From the above description

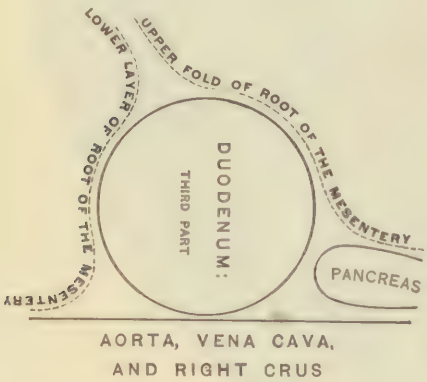

FIG. 890.—Diagram of the third part of the duodenum, to show its peritoneal relations. (Gerrish.)

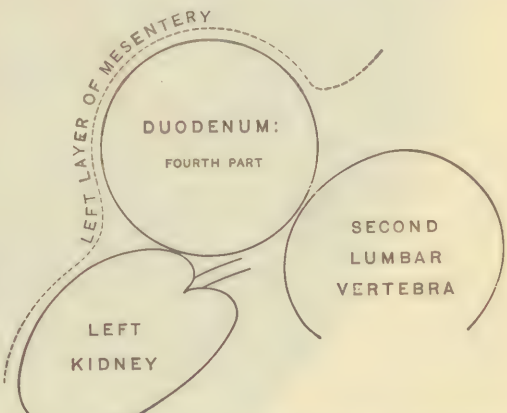

FIG. 891.—Diagram of the fourth part of the duodenum, to show its peritoneal relations. (Gerrish.)

it will be seen that the duodenum may be divided for purposes of description into four portions—**superior, descending, transverse** and **ascending**.

The **First or Superior Portion** (*pars superior*) (Figs. 887, 892, and 894) is very variable in length, but is usually estimated as being about two inches. Beginning at the pylorus, it ends at the level of the neck of the gall-bladder.

[1] Prof. Cunningham's Text-book of Anatomy.

When the stomach is empty this portion of the duodenum is horizontal and transverse; when the stomach is distended it extends from before backward. It is the most movable of the four portions. It is almost completely covered by peritoneum derived from the two layers of the lesser omentum. A small part of its posterior surface is not completely covered by peritoneum (Fig. 888). The first inch of the superior portion of the duodenum is completely covered by peritoneum; the lesser omentum is attached above and the greater omentum below (Fig. 888). The other portion has only its anterior wall covered by peritoneum. The *posterior* and *lateral surfaces* are uncovered by peritoneum and are near the neck of the gall-bladder and the inferior vena cava. The first portion of the duodenum is in such close relation with the gall-bladder that it is usually found to be stained by bile after death, especially on its anterior surface. It is in relation *above* and in *front* with the quadrate lobe of the liver, lying in a slight concavity, the *impressio duodenalis*. It is also in relation *above* in part with the gall-bladder; *behind* with the gastro-duodenal artery, the common bile-duct, and the vena porta; and *below* with the head of the pancreas. The superior portion of the duodenum crosses the transverse fissure of the liver, and by means of the **superior flexure of the duodenum** (*flexura duodeni superior*) passes into the second or descending portion beneath the caudate lobe.

The **Second** or **Descending Portion** (*pars descendens*) (Figs. 887, 892, and 894) is between three and four inches in length, and extends from the neck of the gall-bladder on a level with the first lumbar vertebra along the right side of the vertebral column as low as the body of the fourth lumbar vertebra. It is crossed in its middle third by the transverse colon, the posterior surface of which is uncovered by peritoneum and is connected to the duodenum by a small quantity of connective tissue. The portions of the descending part of the duodenum above and below this interspace are named the **supracolic** and **infracolic portions**, and are covered in front by peritoneum (Fig. 889). The right side of the supracolic portion is covered by peritoneum derived from the anterior surface of the right kidney, the left side of the same portion being covered by the peritoneum forming the lesser sac. The infracolic part is covered by the right leaf of the mesentery. Posteriorly the descending portion of the duodenum is uncovered by peritoneum. The descending portion of the duodenum is in relation, in *front*, with the transverse colon, and above this with the right lobe of the liver, where it lies in the *impressio duodenalis* for the second part of the duodenum; *behind* with the front of the right kidney, to which it is connected by loose areolar tissue, the renal vessels and the vena cava inferior; at its *inner side* is the head of the pancreas, and the ductus communis choledochus; to its *outer side* is the hepatic flexure of the colon. The common bile-duct passes downward behind the first portion of the duodenum, descends to the inner side of the second portion, is joined by the pancreatic duct, and the two ducts perforate the inner side of this portion of the intestine obliquely, and empty into the duodenum by a common opening or by two openings at the summit of a papilla, some three or four inches below the pylorus. The relations of the second part of the duodenum to the right kidney present considerable variations. The descending portion passes into the transverse portion by means of the *flexura duodeni inferior*.

The **Third, Pre-aortic, Horizontal** or **Transverse Portion** (*pars horizontalis inferior*) (Figs. 887, 892, and 894) varies much in length; when the duodenum assumes the ordinary horseshoe form, it measures from two to three inches; but when it presents the rarer V-shaped form, it is practically wanting or very much reduced in length. The transverse portion is described as the horizontal part of the ascending or last portion by those authors who divide the duodenum into three parts instead of four. It commences at the right side of the fourth lumbar vertebra and passes from right to left, with a slight inclination upward, in front of the great

vessels and crura of the Diaphragm, and ends in the fourth portion in front of or just to the left of the abdominal aorta. It is crossed by the superior mesenteric vessels and mesentery. The *posterior surface* rests upon the aorta, the vena cava inferior, and the crura of the Diaphragm. By its upper surface this portion of the duodenum is in relation with the head of the pancreas. The front of the third portion of the duodenum is covered by peritoneum except where the mesenteric vessels and root of the mesentery cross it (Fig. 890). The left side of the termination of the ascending portion is also covered by peritoneum, and in this region the **duodenal fossae** are found (p. 1260).

The **Fourth or Ascending Portion of the Duodenum** (*pars ascendens*) (Figs. 887, 892, and 894) is about two inches long. It ascends on the left side of the vertebral column and aorta, as far as the level of the upper border of the second lumbar vertebra, where it turns abruptly to the right and forward to become the jejunum, forming the **duodeno-jejunal angle** or **flexure** (*flexura duodenojejunalis*)

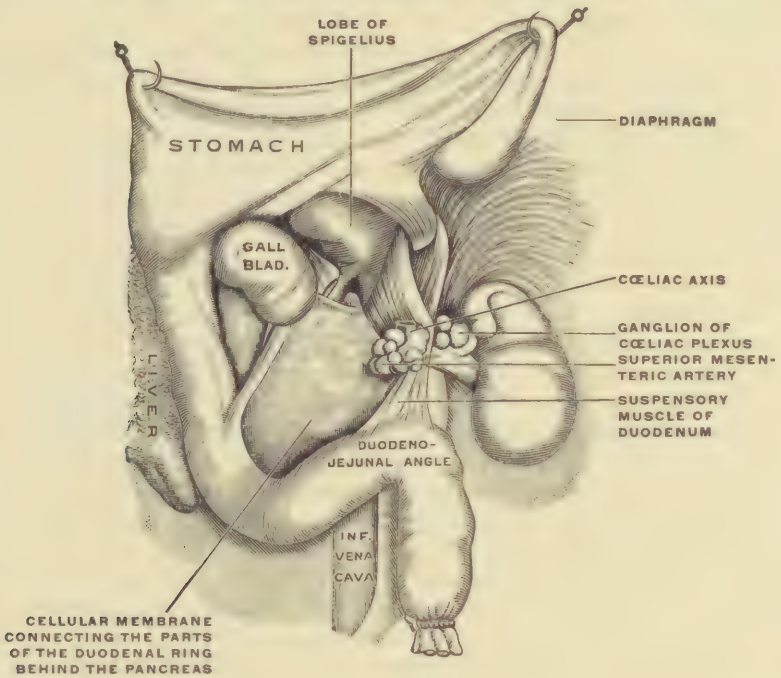

FIG. 892.—Suspensory muscle of the duodenum or muscle of Treitz. (Poirier and Charpy.)

(Fig. 892). It is covered entirely in front and partly at the sides by peritoneum, derived from the left portion of the mesentery (Fig. 891). The superior mesenteric artery and vein are in front of it. It touches the left kidney, slightly overlapping its inner margin, and rests upon the left crus of the Diaphragm.

The first part of the duodenum, as stated above, is somewhat movable, but the rest is practically fixed and is bound down to neighboring viscera and the posterior abdominal wall by the peritoneum. In addition to this, the fourth part of the duodenum and the duodeno-jejunal flexure is further bound down and fixed by a structure called the **Suspensory muscle of the duodenum** or the **suspensory ligament of Treitz** (*m. suspensorius duodeni*) (Fig. 892). This structure commences in the connective tissue around the coeliac axis and left crus of the Diaphragm, and passes downward to be inserted into the superior border of the duodeno-jejunal curve and a part of the ascending duodenum, and from this it is continued into the mesentery. It possesses, according to Treitz, some few plain muscular fibres mixed with the

fibrous tissue, of which it is principally made up. It is of little importance as a muscle, but acts as a suspensory ligament.

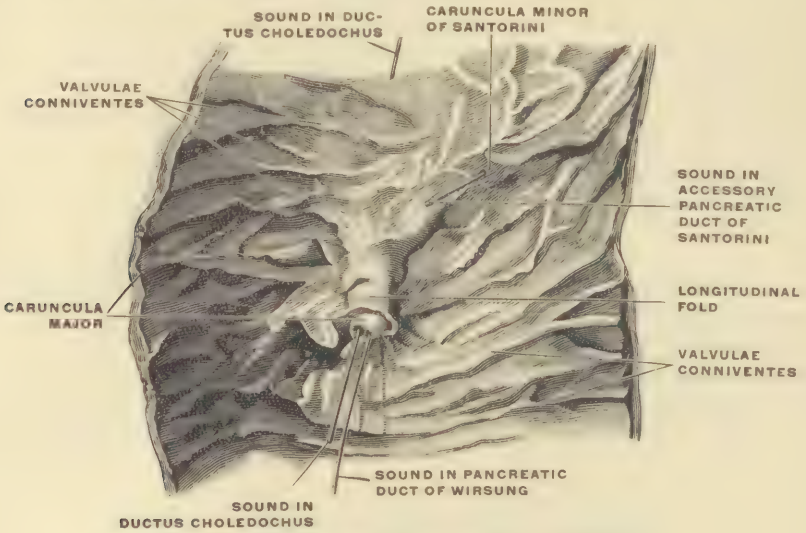

FIG. 893.—The interior of the duodenum. (Spalteholz.)

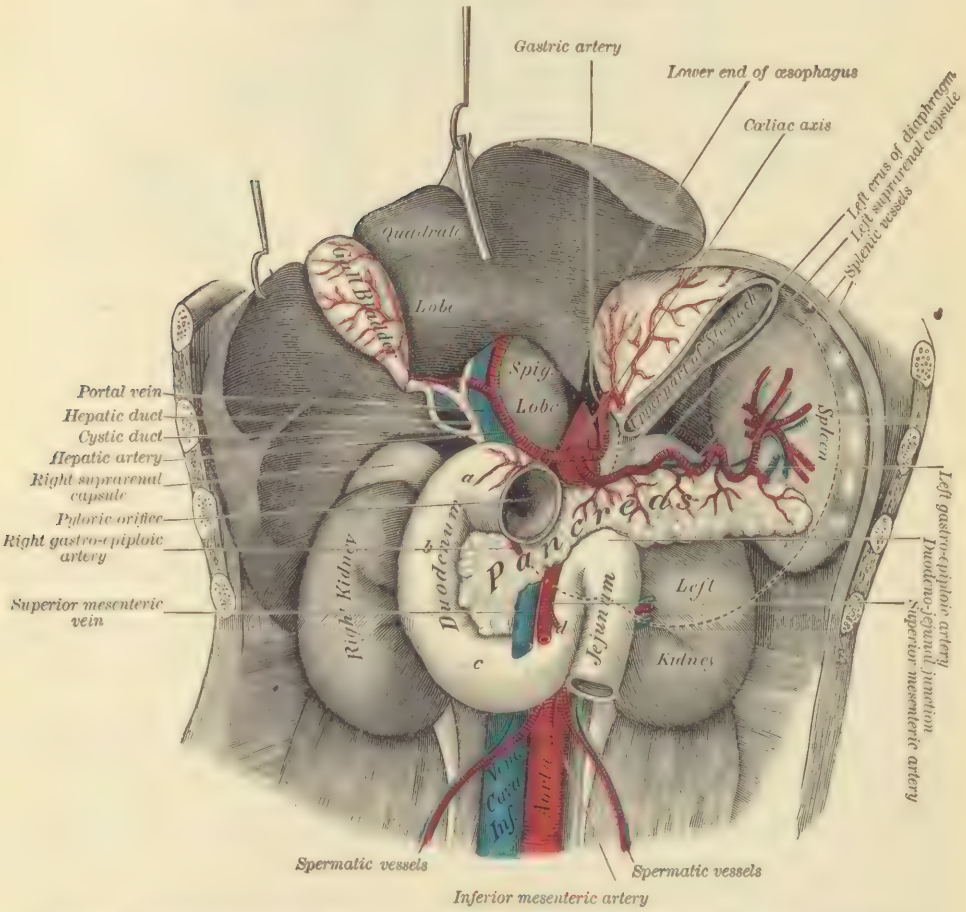

FIG. 894.—The duodenum, its four parts marked *a*, *b*, *c*, *d*. The liver is lifted up; the greater art of the stomach is removed, broken lines indicating its former position. (Testut.)

Interior of the Duodenum (Fig. 893).—In the beginning of the duodenum valvulae conniventes are absent. They begin to appear in the lower half of the first portion, being at first trivial elevations irregularly placed. They become higher, regular, and more numerous lower down, and near the termination of the duodenum are strongly marked and closely placed transverse or spiral folds (Fig. 893 and p. 1291). In the descending portion (Fig. 893) to the side and rear is a longitudinal fold (*plica longitudinalis duodeni*), which is formed by the projection of the bile-duct and pancreatic duct beneath the mucous membrane.

The **caruncula major of Santorini** or the **bile papilla** is a projection or tit in the lower part of the longitudinal fold. At the summit of this papilla are seen two openings, if the bile-duct and pancreatic duct have not united, or one common opening for both of them, if they have united. One inch above and half an inch or more in front of the bile papilla is a much smaller papilla, the **caruncula minor of Santorini** (*papilla duodeni* [*Santorini*]), on the summit of which the accessory pancreatic duct of Santorini opens.

Structure of the Duodenum.—The **peritoneal coat** (*tunica serosa*) has been described. The **muscular coat** (*tunica muscularis*) is practically identical with the muscular coat of the balance of the intestine. The bile-duct and pancreatic duct

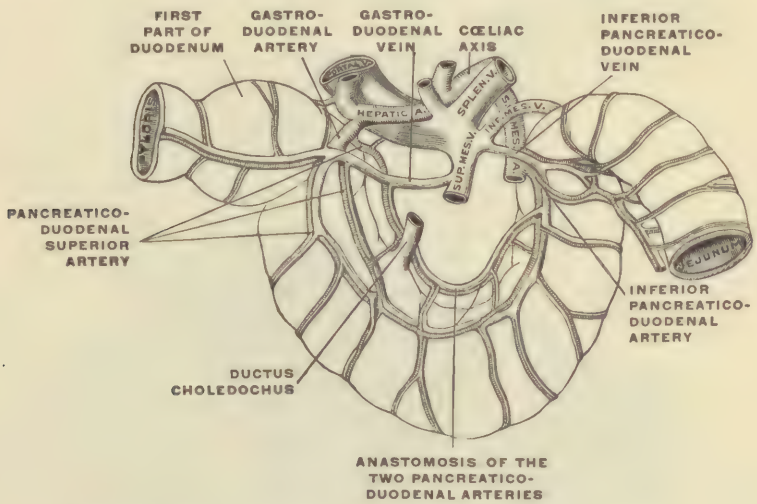

FIG. 895.—The blood-vessels of the duodenum. (Poirier and Charpy.)

pass through it. The **submucous coat** (*tela submucosa*) contains lymph-nodes and **glands of Brunner** (*glandulae duodenales*). These glands are particularly plentiful in the first half of the duodenum (p. 1295). The mucous membrane is thicker in the duodenum than in the rest of the small intestine, is covered with villi, and from the lower half of the first portion down is formed into circular folds or valvulae conniventes. In the descending part it exhibits the previously described longitudinal fold.

Vessels and Nerves.—The **arteries** (Fig. 895) supplying the duodenum are the **pyloric** and **pancreatico-duodenal branches of the hepatic**, and the **inferior pancreatico-duodenal branch of the superior mesenteric**. The **veins** (Fig. 895) correspond to the arteries. The **superior duodenal vein** passes into the superior mesenteric, and the **inferior duodenal vein** passes into the portal. The **lymphatics** pass along with the pancreatico-duodenal arteries, glands being present here and there, and terminate in the glands about the coeliac axis. The **duodenal fossae** are described on p. 1260. The **nerves** are derived from the solar plexus.

The Jejunum and Ileum (Figs. 862, 864, 865, 867, 892).

The remainder of the small intestine from the termination of the duodenum comprises the **jejunum** and **ileum**; the former name being given to the upper two-fifths and the latter to the remaining three-fifths. Spalteholz and others call all of the small intestine below the duodenum the **intestinum tenue mesenteriale**. There is no morphological line of distinction between the jejunum and ileum, and the division is arbitrary; but at the same time it must be noted that the character of the intestine gradually undergoes a change from the commencement of the jejunum to the termination of the ileum, so that a portion of the bowel taken from these two situations would present characteristic and marked differences. These are briefly as follows:

Differences between the Jejunum and Ileum.—If the jejunum high up is contrasted with the ileum low down, it is noted that the former is thicker, of greater diameter, contains more blood-vessels, and hence is more distinctly red, has well-marked valvulae conniventes, but a few small-sized Peyer's patches, and the villi are short and broad. In the ileum large Peyer's patches are present in numbers, and the villi are thin (Prof. Birmingham).

The Jejunum (*intestinum jejunum*).—The jejunum, which derives its name from the Latin word *jejunus* (empty), because it was formerly supposed to be empty after death, is wider, its diameter being about one inch and a half, and is thicker, more vascular, and of a deeper color than the ileum, so that a given length weighs more. Its valvulae conniventes are large and thickly set and its villi are larger than in the ileum. The glands of Peyer are almost absent in the upper part of the jejunum, and in the lower part are less frequently found than in the ileum, and are smaller and tend to assume a circular form. Brunner's glands are only found in the upper part of the jejunum. By grasping the jejunum between the finger and thumb the valvulae conniventes can be felt through the walls of the gut; these being absent in the lower part of the ileum, it is possible in this way to distinguish the upper from the lower part of the small intestine.

The Ileum (*intestinum ileum*).—The ileum (so called from the Greek word *εἰλεῖν*, *to twist*, on account of its numerous coils and convolutions) is placed below and to the right of the jejunum. It is narrower, its diameter being one inch and a quarter, and its coats are thinner and less vascular than those of the jejunum. It possesses but few valvulae conniventes, and they are small and disappear entirely toward its lower end, but Peyer's patches are larger and more numerous. The jejunum for the most part occupies the umbilical and left iliac regions, while the ileum occupies chiefly the umbilical, hypogastric, right iliac, and pelvic regions, and terminates in the right iliac fossa by opening into the inner side of the commencement of the large intestine. The upper portion of the jejunum passes to the left of the duodeno-jejunal flexure, and is in relation with the under surface of the pancreas and the transverse mesocolon. The lower portion of the ileum is in the pelvis and rises from above the brim, passing upward, backward, and to the right to reach the ileo-caecal opening. Treves points out that another portion of the small intestine may be in the pelvis, viz., the portion with the longest mesentery. This is a portion somewhere between a point six feet from the duodenum and a point eleven feet from the duodenum. The jejunum and ileum are attached to the posterior abdominal wall by an extensive fold of peritoneum, the **mesentery** (p. 1257), which allows the freest motion, so that each coil can accommodate itself to changes in form and position. The mesentery is fan-shaped; its posterior border, about six inches in length, is attached to the abdominal wall from the left side of the second lumbar vertebra to the right iliac fossa (Fig. 862). Its length is about eight inches from its commencement to its termination at the intestine, and it is rather longer about its centre than at either end of the bowel. According to Lockwood,

it tends to increase in length as age advances. Between the two layers of which it is composed are contained blood-vessels, nerves, lacteals, and lymphatic glands, together with a variable amount of fat.

Meckel's Diverticulum (*diverticulum ilei*).—Occasionally there may be found connected with the lower part of the ileum, on an average about three feet from its termination, a blind diverticulum or tube, varying in length, but averaging about two inches, and being of about the same diameter as the piece of intestine of which it is a part. Sometimes only a portion of the proximal end is open and the balance of the structure is obliterated and shrunk to a fibrous cord. In other cases the diverticulum is actually of greater diameter than the intestine. It usually is at a right angle to the intestine, but may take almost any direction. In most cases it has a mesentery. It is attached to and communicates with the lumen of the bowel by one extremity, and by the other is unattached or may be connected with the abdominal wall or with some other portion of the intestine by a fibrous band. This is Meckel's diverticulum, and represents the remains of the **vitelline** or **omphalo-mesenteric duct**, the duct of communication between the umbilical vesicle and the alimentary canal in early fœtal life.

Structure of the Small Intestine, including the Duodenum.—The wall of the small intestine is composed of four coats—**serous, muscular, areolar** or **submucous,** and **mucous.**

The Serous Coat (*tunica serosa*).—The relation of the peritoneum to the duodenum has been described. The remaining portion of the small intestine is surrounded by the peritoneum, excepting along its attached or mesenteric border; here a space is left for the vessels and nerves to pass to the gut.

The Muscular Coat (*tunica muscularis*).—The muscular coat consists of two layers of fibres, an **external** or **longitudinal layer** and an **internal** or **circular layer.**

The **Longitudinal Fibres** (*stratum longitudinale*) are thinly scattered over the surface of the intestine, and are more distinct along its free border.

The **Circular Fibres** (*stratum circulare*) form a thick, uniform layer; they surround the cylinder of the intestine in the greater part of its circumference, and are composed of plain muscle-cells of considerable length. The muscular coat is thicker at the upper than at the lower part of the small intestine.

The Areolar or Submucous Coat (*tela submucosa*).—The areolar or submucous coat connects together the mucous and muscular layers. It consists of loose, filamentous areolar tissue, which forms a bed for the subdivision of the nutrient vessels, previous to their distribution to the mucous surface.

The submucous coat contains **lymph-nodules** (*noduli lymphatici*). Each nodule is pyramidal or pear-shaped, and the apex lies in the mucous membrane and forms a rounded elevation. These rounded elevations mark the solitary glands and Peyer's patches (Figs. 896, 898, and 905), and in nowise resemble villi. In the duodenum the submucous tissue contains the **duodenal glands.** The submucous tissue is prolonged into the **valvulae conniventes.** It contains blood-vessels, Meissner's plexus of nerves, and lymph-vessels.

The Mucous Membrane (*tunica mucosa*).—The mucous membrane is thick and highly vascular at the upper part of the small intestine, but somewhat paler and thinner below. It consists of the following structures: next the areolar or submucous coat is a layer of unstriped muscular fibres, the **muscularis mucosae**; internal to this is a quantity of retiform tissue, enclosing in its meshes lymph-corpuscles, and in which the blood-vessels and nerves ramify. Lastly, a basement-membrane, supporting a single layer of epithelial cells, which throughout the intestines are columnar in character. They are granular in appearance, and each possesses a clear, oval nucleus. At their superficial or unattached end they present a distinct layer of highly refracting material, marked by vertical striae, which were formerly

believed to be minute channels by which the chyle was taken up into the interior of the cell, and by them transferred to the lacteal vessels of the mucous membrane.

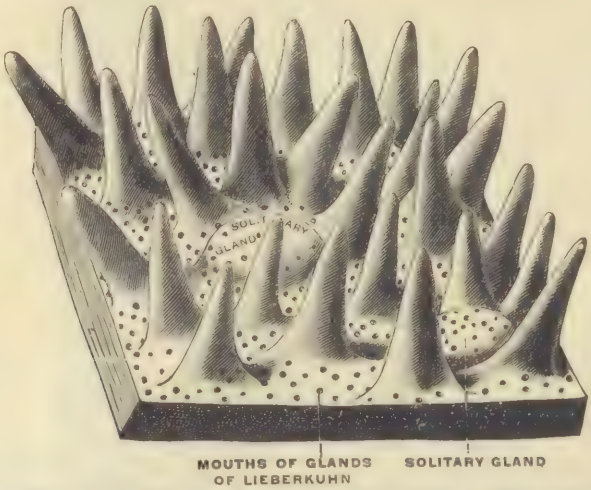

FIG. 896.—Free surface of the mucous membrane of the small intestine, showing villi, solitary glands, and openings of the intestinal glands. Semidiagrammatic. (Testut.)

The mucous membrane presents for examination the following structures contained within it or belonging to it:

Valvulae conniventes.	Duodenal glands.
Villi.	Lymphatic nodules { Solitary glands.
Simple follicles.	Lymphatic nodules { Peyer's or agminate glands.

The **Valvulae Conniventes** or the **Valves of Kerkring** (*plicae circulares* [*Kerkringi*]) (Fig. 897) are large folds or valvular flaps projecting into the lumen of the bowel. They are composed of reduplications or folds of the mucous membrane, the two layers of the fold being bound together by submucous tissue; they contain no muscular fibres, and, unlike the folds in the stomach, they are permanent, and are not obliterated when the intestine is distended. The majority extend transversely across the cylinder of the intestine for about one-half or two-thirds of its circumference, but some form complete circles, and others have a spiral direction; the latter usually extend a little more than once around the bowel, but occasionally two or three times. The spiral arrangement is the characteristic one of the shark family of fishes. The larger folds are about one-third of an inch in depth at their broadest part; but the greater number are of smaller size. The larger and smaller folds alternate with each other. They are not found at the commencement of the duodenum, but begin to appear about one or two inches beyond the pylorus. In the lower part of the descending portion, below the point where the bile and pancreatic ducts enter the intestine, they are very large and closely approximated. In the transverse portion of the duodenum and upper half of the jejunum they

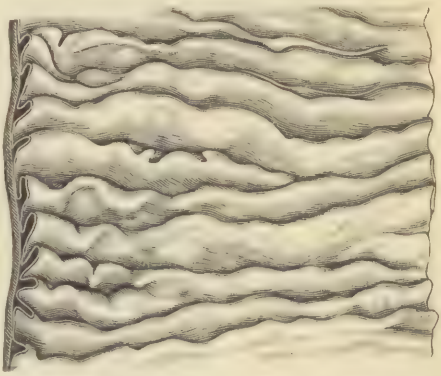

FIG. 897.—Valvulae conniventes in the upper part of the small intestine. (Poirier and Charpy.)

are large and numerous; and from this point, down to the middle of the ileum, they diminish considerably in size. In the lower part of the ileum they almost entirely disappear; hence the comparative thinness of this portion of the intestine as compared with the duodenum and jejunum. The valvulae conniventes retard the passage of the food along the intestine, and afford a more extensive surface for absorption.

The **Villi** (*villi intestinales*) (Figs. 896, 898, 899, 900, and 905) are minute, highly vascular processes, never larger than one millimetre, projecting from the mucous membrane of the small intestine throughout its whole extent, and giving to its surface a velvety appearance. They spring from the valvulae conniventes and also from the spaces between them. In shape, according to Rauber, they are short and leaf-shaped in the duodenum, tongue-shaped in the jejunum, and filiform

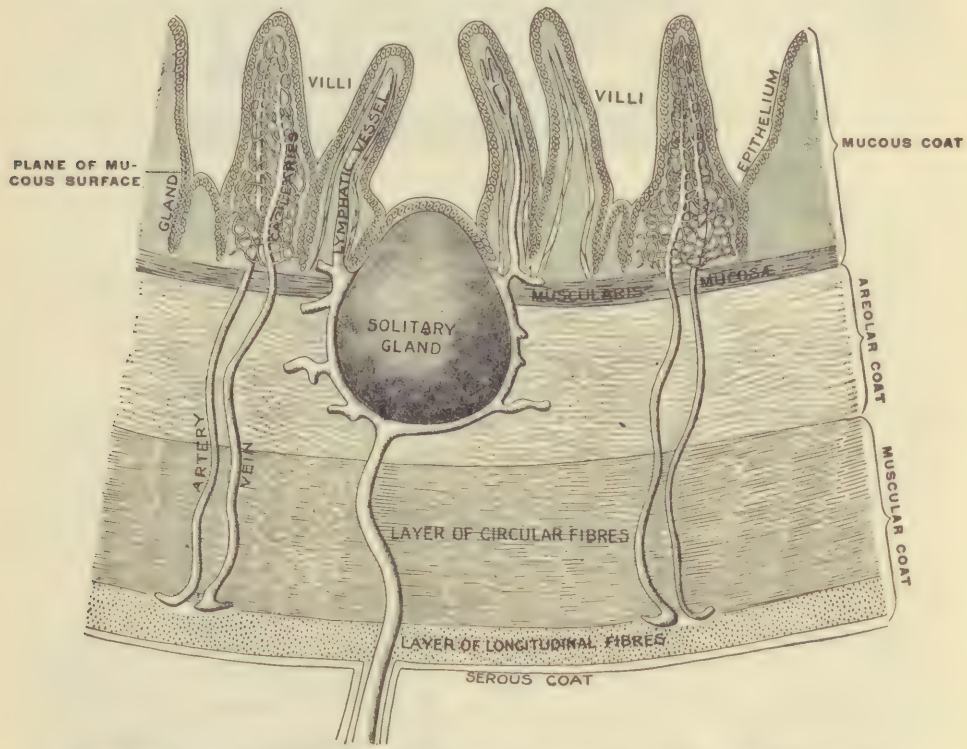

FIG. 898.—Mucosa of small intestine in ideal vertical cross-section. (Testut, after Heitzmann.)

in the ileum. They are largest and most numerous in the duodenum and jejunum, and become fewer and smaller in the ileum. Krause estimates their number in the upper part of the small intestine at from fifty to ninety in a square line; and in the lower part from forty to seventy, the total number for the whole length of the intestine being about four millions.

STRUCTURE OF THE VILLI (Figs. 899 and 900).—The structure of the villi has been studied by many eminent anatomists. We shall here follow the description of Watney,[1] whose researches have a most important bearing on the physiology of that which is the peculiar function of this part of the intestine, the absorption of fat.

The essential parts of a villus are—the lacteal vessel, the blood-vessels, the epithelium, the basement-membrane and muscular tissue of the mucosa, these structures being supported and held together by retiform lymphoid tissue.

[1] Phil. Trans., vol. clxv. part ii.

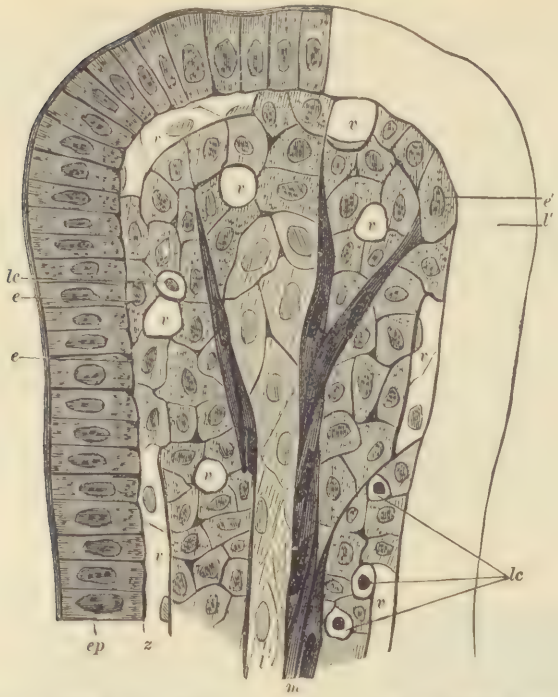

FIG. 899.—Diagrammatic section of a villus. *ep*. Epithelium only partially shaded in. *l*. Central chyle-vessel; the cells forming the vessel have been less shaded to distinguish them from the cells of the parenchyma of the villus. *m*. Muscle-fibres running up by the side of the chyle-vessel. It will be noticed that each muscle-fibre is surrounded by the reticulum, and by this reticulum the muscles are attached to the cells forming the membrana propria, as at *e'*, or to the reticulum of the villus. *lc*. Lymph-corpuscles, marked by a spherical nucleus and a clear zone of protoplasm. *l'*. Upper limit of the chyle-vessel. *e, e, e'*. Cells forming the membrana propria. It will be seen that there is hardly any difference between the cells of the parenchyma, the endothelium of the upper part of the chyle-vessel, and the cells of the membrana propria. V. Blood-vessels. *z*. Dark line at base of the epithelium formed by the reticulum. It will be seen that the reticulum penetrates between all the other elements of the villus. The reticulum contains thickenings or "nodal points." The diagram shows that the cells of the upper part of the villus are larger and contain a larger zone of protoplasm than those of the lower part. The cells of the upper part of the chyle-vessel differ somewhat from those of the lower part in that they more nearly resemble the cells of the parenchyma. (Watney.)

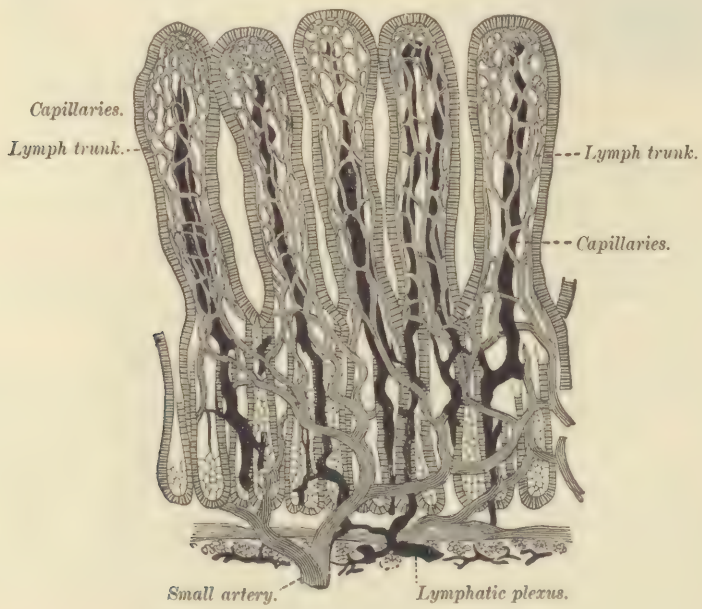

FIG. 900.—Villi of small intestine. (Cadiat.)

These structures are arranged in the following manner: situated in the centre of the villus is the **lacteal**, terminating near the summit in a blind extremity; running along this vessel are unstriped muscular fibres; surrounding it is a plexus of capillary vessels, the whole being enclosed by a basement-membrane, and covered by columnar epithelium. Those structures which are contained within the basement-membrane—namely, the lacteal, the muscular tissue, and the blood-vessels—are surrounded and enclosed by a delicate reticulum which forms the matrix of the villus, and in the meshes of which are found large, flattened cells with oval nuclei, and, in smaller numbers, lymph-corpuscles. These latter are to be distinguished from the larger cells of the villus by their behavior with reagents, by their size, and by the shape of the nucleus, which is spherical. Transitional forms, however, of all kinds are met with between the lymph-corpuscles and the proper cells of the villus. Nerve-fibres are contained within the villi; they form ramifications throughout the reticulum.

The **lacteals** are in some cases double, and in some animals *multiple*. Situated in the axis of the villi, they commence by dilated cæcal extremities near to, but not quite at, the summit of the villus. The walls are composed of a single layer of endothelial cells, the interstitial substance between the cells being continuous with the reticulum of the matrix.

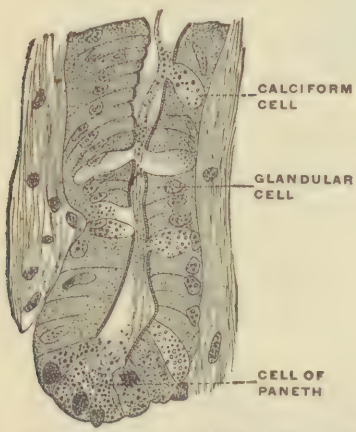

FIG. 901.—Section of a gland of Lieberkühn in the mouse. (Paneth.)

FIG. 902.—Transverse section of crypts of Lieberkühn. (Klein and Noble Smith.)

The **muscular fibres** are derived from the muscularis mucosæ, and are arranged in bundles around the lacteal vessel, extending from the base to the summit of the villus, and giving off laterally individual muscle-cells, which are enclosed by the reticulum, and by it are attached to the basement-membrane.

The **blood-vessels** form a plexus between the lacteal and the basement-membrane, and are enclosed in the reticular tissue; in the interstices of the capillary plexus, which they form, are contained the cells of the villus.

These structures are surrounded by the basement-membrane, which is made up of a stratum of endothelial cells, and upon which is placed a layer of columnar epithelium. The reticulum of the matrix is continuous through the basement-membrane (that is, through the interstitial substance between the individual endothelial cells) with the interstitial cement substance of the columnar epithelial cells on the surface of the villus. Thus we are enabled to trace a direct continuity between the interior of the lacteal and the surface of the villus by means of the reticular tissue, and it is along this path that the chyle passes in the process of absorption by the villi; that is to say, it passes first of all into the columnar

epithelial cells, and, escaping from them, is carried into the reticulum of the villus, and thence into the central lacteal.

The **Simple Follicles, Intestinal Glands, Crypts** or **Glands of Lieberkühn** (*glandulae intestinales* [*Lieberkuhni*]) (Figs. 901, 902, and 905) are found in considerable numbers over every part of the mucous membrane of the small intestine. They consist of minute tubular depressions of the mucous membrane, arranged perpendicularly to the surface, upon which they open by small circular apertures. They may be seen with the aid of a lens, their orifices appearing as minute dots scattered between the villi (Fig. 896). Their walls are thin, consisting of a basement-membrane lined by columnar epithelium, and covered on their exterior by capillary vessels.

The **Duodenal** or **Brunner's Glands** (*glandulae duodenales* [*Brunneri*]) are limited to the duodenum and commencement of the jejunum. They are small, flattened, granular bodies embedded in the submucous areolar tissue, and open upon the surface of the mucous membrane by minute excretory ducts. They are most numerous and largest near the pylorus. They are small, compound, acino-tubular glands, and much resemble the small glands which are found in the mucous membrane of the mouth. They are believed by Watney to be direct continuations of the pyloric glands of the stomach. They consist of a number of tubular alveoli, lined by epithelium, and opening by a single duct on the inner surface of the intestine.

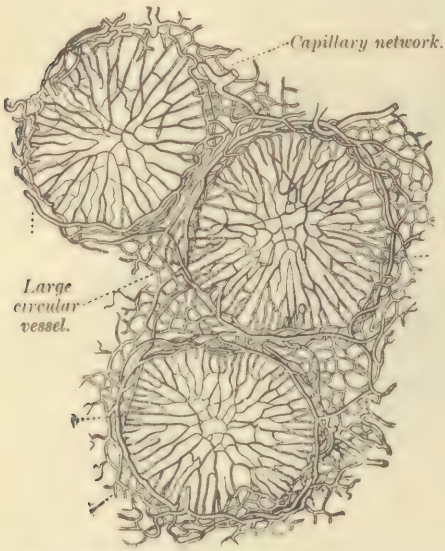

FIG. 903.—Transverse section through the equatorial plane of three of Peyer's follicles from the rabbit.

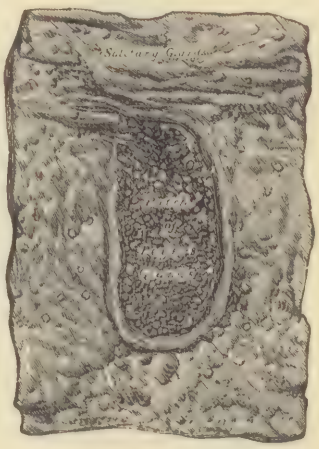

FIG. 904.—Patch of Peyer's glands. From the lower part of the ileum.

The **Lymph Nodules** (*noduli lymphatici*) are small pyriform structures. The bodies of the nodes are in the submucous coat; the apices are in the mucous membrane, which is thrown by them into rounded elevations. They are divided into **solitary glands** and **Peyer's glands.**

The **solitary glands** (*noduli lymphatici solitarii*) (Figs. 896 and 898) are found scattered throughout the mucous membrane of the small intestine and the large intestine. In the small intestine they are most numerous in the lower part of the ileum, upon and between the valvulae conniventes. They are small, round, whitish bodies, from one-twenty-fourth of an inch to one-quarter of an inch in diameter. Their free surface is covered with villi, and each gland is surrounded by the

openings of the follicles of Lieberkühn. They are now recognized as lymph-nodules. They consist of a dense interlacing retiform tissue closely packed with lymph-corpuscles and permeated with an abundant capillary network. The interspaces of the retiform tissue are continuous with larger lymph-spaces at the base of the gland, through which they communicate with the lacteal system. They are situated partly in the submucous tissue, partly in the mucous membrane, whence they form slight projections of its epithelial layer, after having penetrated the muscularis mucosae. The villi situated on them are generally absent from the very summit (or "cupola," as Frey calls it) of the gland.

Peyer's glands, Peyer's patches, the **agminated glands** or the **tonsillae intestinales** (*noduli lymphatici aggregati* [*Peyeri*]) (Figs. 903, 904, and 905) may be regarded as aggregations of solitary glands, forming circular or oval patches from twenty-five to forty in number, and varying in length from half an inch to four inches. They are largest and most numerous in the ileum. In the lower part of the jejunum they are small, of a circular form, and few in number. They are occasionally seen in the duodenum. They are placed lengthwise in the intestine, and are situated

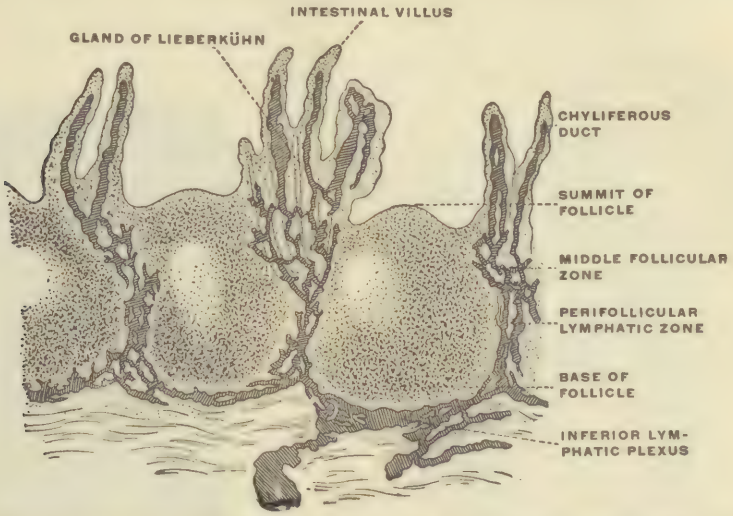

Fig. 905.—Vertical cell of a Peyer's patch in a man with the lymphatic vessels injected. (Frey.)

in the portion of the tube most distant from the attachment of the mesentery. Each patch is formed of a group of the above-described solitary glands covered with mucous membrane, and in almost every respect are similar in structure to them. They do not, however, as a rule, possess villi on their free surface. Each patch is surrounded by a circle of the crypts of Lieberkühn. They are best marked in the young subject, becoming indistinct in middle age, and sometimes altogether disappearing in advanced life. They are largely supplied with blood-vessels, which form an abundant plexus around each follicle and give off fine branches which permeate the lymphoid tissue in the interior of the follicle. The lacteal plexuses which are found throughout the small intestine are especially abundant around these patches; here they form rich plexuses with sinuses around the glands (Fig. 905). In typhoid fever there is ulceration of Peyer's patches.

Vessels and Nerves.—The **arteries** (*vasa intestini tenuis*) are branches of the **superior mesenteric** (Fig. 420) and ascend within the mesentery, forming single, double, or even tertiary loops (Figs. 869, 870, 871, 872, 873, 874, and 906). The terminal branches reach the intestine, and each branch divides into two, one going to each side of the intestine and passing transversely around it. At first they are

directly beneath the peritoneum, but after a time they pass to the submucosa and form a plexus, from which branches go to the mucous membrane. Some of these enter the villi; others form plexuses about the glands of Lieberkühn (Birmingham).

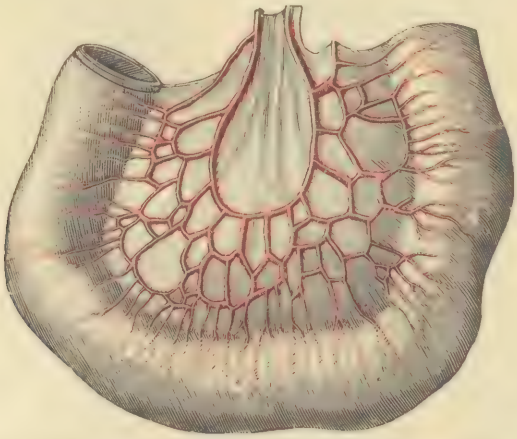

FIG. 906.—A loop of small intestine, showing the mode of distribution of the arteries. (Testut.)

Dr. George H. Monks[1] points out that opposite the upper portion of the bowel the mesenteric vessels form only primary loops; as we pass down secondary loops appear, become larger and more and more numerous, and actually prominent features about the fourth foot. As we descend the secondary loops become larger and more numerous and the primary become smaller. All the time the loops get nearer and nearer to the bowel. Tertiary loops may appear. Opposite the lower part of the ileum the loops cease to be characteristic and they form a network. (Monks's views are fully set forth on pp. 1266, 1267, and 1268.) In the upper part of the gut the vasa recta are from 3 to 5 cm. long, when the loop of small intestine to which they run is lifted up so as to put them gently on the stretch. They are straight, large, and regular, and rarely give off branches in the mesentery. In the lower third they are very short, being generally less than 1 cm. in length. Here they are less straight, smaller, less regular, and have frequent branches in the mesentery.

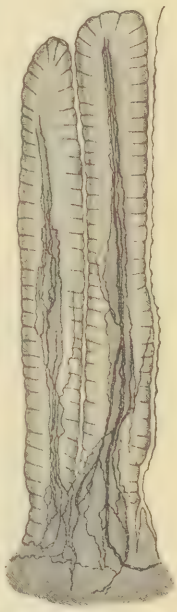

FIG. 907. Nerve endings in the villi of the small intestine of a rabbit. (Müller.)

The **veins** correspond to the arteries, and the venous blood passes to the **superior mesenteric vein**, which, it will be remembered, unites with the splenic vein to form the portal vein. The mesenteric veins are devoid of valves.

The **lacteals** are **lymphatics** (Figs. 898, 899, 900, and 905) which arise in the villi. Lymphatics also begin in sinuses at the base of the solitary glands and as *lymph-nodes* in the submucous coat. Peyer's patches are aggregations of lymph-nodes. There is an extensive lymphatic plexus in the submucous coat, another in the muscular coat, another under the peritoneum. The submucous plexus is formed by lymphatics from the villi and mucous membrane. This plexus is joined by lymphatics from the bases of the solitary glands, and the lymph passes by vessels to larger vessels at the mesenteric border of the gut. The muscular lymphatics are placed between the two muscular layers. They

[1] Annals of Surgery, May, 1903.

form a plexus and communicate freely with the lymphatics from the mucous membrane, and empty themselves in the same manner into the commencement

Fig. 908. Meissner's plexus.

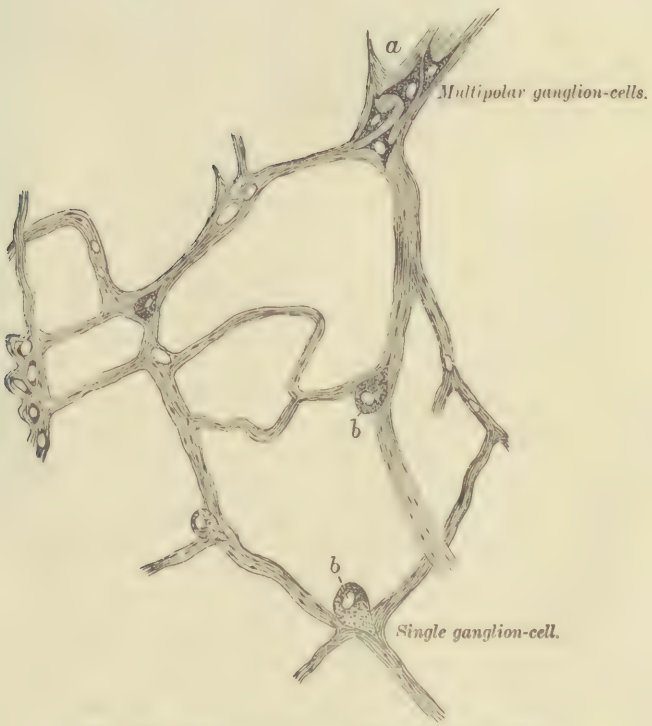

Fig. 909.—Meissner's plexus. (Klein and Noble Smith.)

of the lacteal vessels at the attached border of the gut. The vessels from all sources of lymphatic supply pass up between the two layers of the mesentery, being connected with the **mesenteric glands** (Fig. 509), and unite to form a trunk, the **intestinal lymphatic trunk**, which opens into the receptaculum chyli, or the vessels unite to form several trunks, which open separately into the receptaculum chyli.

The **nerves of the small intestine** (Figs. 907, 908, and 909) are derived from the **coeliac plexus** about the superior mesenteric artery, which is one of the divisions of the **solar plexus.** They pass along within the mesentery with the superior mesenteric artery and reach the intestine. They pass to the plexus of nerves and ganglia situated between the circular and longitudinal muscular fibres (**Auerbach's plexus**), from which the nervous branches are distributed to the muscular coats of the intestine. From this plexus a secondary plexus is derived (**Meissner's plexus**). It is formed by branches which have perforated the circular muscular fibres (Fig. 909). This plexus lies between the muscular and mucous coats of the intestine. It is also gangliated, and from it the ultimate fibres pass to the muscularis mucosae, to the villi, and to the mucous membrane. The nerves of the intestine are non-medullated, and some of the fibres are derived from the pneumogastric.

THE LARGE INTESTINE (INTESTINUM CRASSUM) (Figs. 799, 861, 865, 910, 911).

The large intestine extends from the termination of the ileum to the anus. It is about five feet or more in length, being one-fifth of the whole extent of the

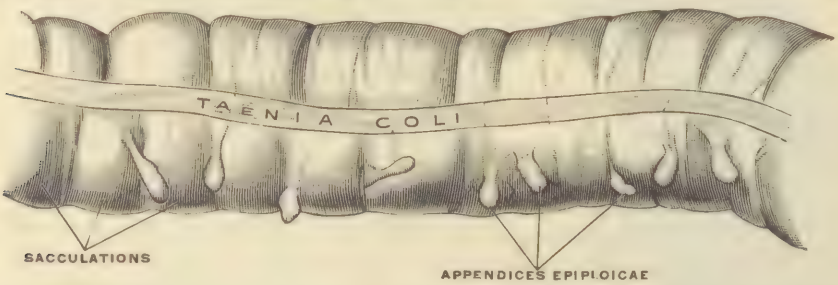

FIG. 910.—Large intestine. A piece of transverse colon from a child two years old. The three chief characteristics of the large intestine—sacculation, taeniae and appendices epiploicae—are shown. (Cunningham.)

intestinal canal. It is largest at its commencement at the caecum, and gradually diminishes as far as the rectum, where there is a dilatation of considerable size just above the anus. The diameter of the distended caecum is usually about three inches; the diameter of the descending colon is about one and a half inches. The large intestine differs from the small intestine in its greater size, its more fixed position, its sacculated form (Figs. 910 and 911), and in possessing certain appendages to its external coat, the **appendices epiploicae** (Fig. 910). The appendices epiploicae are peritoneal pouches containing fat, unless the subject is greatly wasted; they protrude here and there from the peritoneal coat of the entire large bowel, except the rectum, and are particularly frequent along the anterior longi-

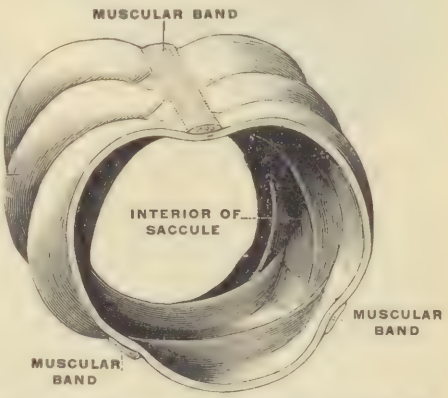

FIG. 911.—Segment of large intestine, showing the characteristic features of its structure. (Testut.)

tudinal band. Further, the longitudinal muscular fibres of the large intestine do not form a continuous layer around the gut, but are arranged in three **longitudinal bands** or **taeniae** (*taeniae coli*) (Fig. 911). The large intestine, in its course, describes an arch, which surrounds the convolutions of the small intestine. It commences in the right inguinal region, in a dilated part, the **caecum.** It ascends through the right lumbar and right hypochondriac regions to the under surface of the liver; it here takes a bend to the left, the **hepatic flexure,** and passes transversely across the abdomen on the confines of the epigastric and umbilical regions, to the left hypochondriac region; it then bends again, the **splenic flexure,** and descends through the left lumbar region to the left iliac fossa, where it becomes convoluted, and forms the **sigmoid flexure;** finally it enters the pelvis, and descends along its posterior wall to the anus. The large intestine is divided into the **caecum, colon,** and **rectum.**

The Caecum (Intestinum Caecum) (Figs. 912, 913).

The caecum, the commencement of the large intestine, is the large blind pouch, or *cul-de-sac*, situated below the ileo-caecal valve. Its name is derived from *caecus, blind.* Its blind end or fundus is directed downward, and its open end upward, communicating directly with the colon, of which this blind pouch appears to be the beginning or head, and hence the old name **caput caecum coli** was applied to it. An incomplete groove marks the upper limit of the caecum. This groove is at the level of the opening of the ileum. When the caecum is contracted it bends on this groove as on a hinge and forms an angle with the ascending colon. In the contracted caecum sacculations are but slightly evident; in the distended caecum they are definite. Its size is variously estimated by different authors, but on an average it may be said to be two and a half inches in length and three in breadth. In 435 careful autopsies, Byron Robinson found the caecum and appendix congenitally absent in one case.[1] The same author says that excessively large caeca are found in a little less than one-third of all autopsies. A large caecum may be four inches in width, entirely surrounded by peritoneum and usually is excessively mobile. Sometimes an excessively small caecum is encountered. According to Byron Robinson, this results from diminution of the blood-supply during the axial rotation and caecal descent of development. An adult caecum may be only one inch in width and one-half an inch in length, and it is usually devoid of mobility. It is situated in the right iliac fossa, above the outer half of Poupart's ligament, usually rests on the Ilio-psoas muscle, the iliac fascia intervening, and lies immediately behind the abdominal wall. The right side of the caecum is in contact with the outer wall of the abdomen, and the outer aspect of the anterior wall of the caecum is in contact with the anterior abdominal wall (Spalteholz). When the caecum is full the small intestine lies in front of the left

FIG. 912.—The caecum and colon laid open to show the ileo-caecal valve.

[1] St. Louis Courier of Medicine, October–December, 1902.

side and lower portion of the anterior caecal wall. If the caecum is empty the small intestine lies in front of its anterior wall, and the lower end is on a higher level than when this portion of the gut is full. In 15 per cent. of cases the caecum is covered by the omentum (Byron Robinson). Byron Robinson describes four positions of the caecum: 1. On the Psoas muscle. 2. To the right of the Psoas muscle. 3. In the pelvis. 4. The potential position, in which it lies free in the abdominal cavity. It may be found in various positions in the abdomen, because of elongation of the fixation apparatus. The commonest position is on the Psoas muscle, and this position is even more common in men than in women. It is twice as often in the pelvis in women as in men—20 per cent. of cases in the former; 10 per cent. in the latter. As a rule, it is entirely enveloped on all sides by peritoneum, but in a certain number of cases (6 per cent., according to Berry) the peritoneal covering is not complete, so that a small portion of the upper end of the posterior surface is uncovered and connected to the iliac fascia by connective tissue. As a matter of fact, there is no real **mesocaecum**—meaning by the term a peritoneal fold which holds the caecum to the dorsal wall of the abdomen—except when there is failure in development. The normal caecum is completely invested by peritoneum from the beginning. Originally the caecum receives its blood along a single peritoneal fold, the **ileo-caecal fold,** which is a simple mesentery. As development advances, this simple mesentery becomes a double fold and practically bloodless, and is replaced by two vascular folds, the **mesoappendix** to the left and the **mesenterico-colicum** to the right. The mobility of the caecum varies. Very small caeca are fixed. In most cases the caecum lies quite free in the abdominal cavity and enjoys a considerable amount of movement. Sometimes it is excessively mobile, and in such cases is usually also of large size. Such mobility is due to a stretched fixation apparatus. A very large and mobile caecum may be made to come in contact with any abdominal viscus and may enter any hernial sac on either side. As a rule, when the caecum is large and mobile, it is found in the pelvis or in the middle of the abdomen (Byron Robinson). It is to be remembered that a mobile caecum carrying with it the appendix may pass to almost any region of the abdomen. Sometimes the caecum fails to descend or only descends a part of the way during development, the axial rotation of the intestinal tract having been arrested. In such a case it may terminate at the level of the gall-bladder, and the ascending colon is absent. In 310 adult males Byron Robinson found 8 per cent. with undescended caecum and appendix. Non-descent is found in less than 4 per cent. of adult females. A *partly descended* caecum usually lies upon the right kidney.

The caecum varies in shape, but, according to Treves, in man it may be classified under one of four types (Fig. 913). In early fœtal life it is short, conical, and broad at the base, with its apex turned upward and inward toward the ileo-caecal junction. It then resembles the caecum of some of the monkey tribe, *e. g.*, Mangabey monkey. As the fœtus grows the caecum increases in length more than in breadth, so that it forms a longer tube than in the primitive form and without the broad base, but with the same inclination inward of the apex toward the ileo-caecal junction. This form is seen in others of the monkey tribe, *e. g.*, the spider monkey. As development goes on, the lower part of the tube ceases to grow and the upper part becomes greatly increased, so that at birth there is a narrow tube, the **vermiform appendix,** hanging from a conical projection, the **caecum**. This is the **infantile form,** and as it persists throughout life, in about 2 per cent. of cases, it is regarded by Treves as the *first* of his four types of human caeca. The caecum is conical and the appendix rises from its apex. The three longitudinal bands start from the appendix and are equidistant from each other. In the *second* type, the conical caecum has become quadrate by the growing out of a saccule on either side of the anterior longitudinal band. These saccules are of equal size,

and the appendix arises from between them, instead of from the apex of a cone. This type is found in about 3 per cent. of cases. The *third* type is the normal type of man. Here the two saccules, which in the second type were uniform, have grown at unequal rates: the right with greater rapidity than the left. In consequence of this an apparently new apex has been formed by the growing downward of the right saccule, and the original apex, with the appendix attached, is pushed over to the left toward the ileo-caecal junction. The three longitudinal bands still start from the base of the appendix, but they are now no longer equidistant from each other, because the right saccule has grown between the anterior and postero-external bands, pushing them over to the left. This type occurs in about 90 per cent. of cases. The *fourth* type is merely an exaggerated condition of the third;

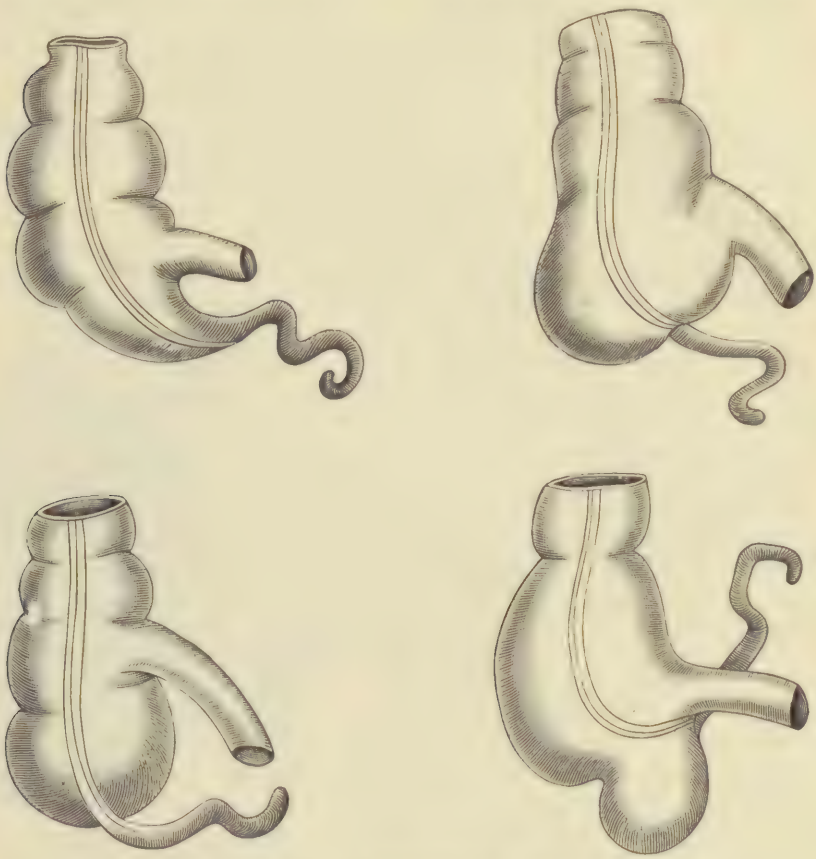

FIG. 913.—The four types of caecum.

the right saccule is still larger, and at the same time the left saccule has been atrophied, so that the original apex of the caecum, with the appendix, is close to the ileo-caecal junction, and the anterior band courses inward to the same situation. This type is present in about 4 per cent. of cases.

Supports of the Caecum.—According to Byron Robinson,[1] the caecum is maintained in position by the mesocolon and a peritoneal fold, the **right phrenico-colic ligament,** which arises from the **hepato-duodenal** and **hepato-renal ligaments**. It receives support from the connective tissue about vessels and nerves, and inconstantly from folds which fixes it in the iliac fossa and in the region of the vena cava.

[1] St. Louis Courier of Medicine, October-December, 1902.

The Interior of the Caecum.—In the interior of the caecum are seen depressions which correspond to the surface **haustra,** and **semilunar folds** (*plicae semilunares coli*) (Fig. 912), which correspond to the transverse surface constrictions. There are three openings in the caecum: that into the colon; that into the ileum, which is guarded by the **ileo-caecal valve** (p. 1308); and that into the appendix, which may be guarded by the **valve of Gerlach.**

Pericaecal Folds and Fossae.—See p. 1262, and Figs. 866, 867, and 868.

The Vermiform Appendix (*processus vermiformis*) (Figs. 866, 867, 868, 913, 914, 915, 916, and 918).—The vermiform appendix is found only in man, the higher apes, and the wombat, although in certain rodents a somewhat similar arrangement exists. In carnivorous animals the caecum is very slightly developed; in herbivorous animals (with a simple stomach) it is, as a rule, extremely large. It has been suggested that the vermiform process in man is the degenerated remains of the herbivorous caecum, which has been replaced by the carnivorous form.[1] The vermiform appendix is a long, narrow, worm-shaped, musculo-membranous tube, which starts from what was originally the apex of the caecum. After development has advanced the vermiform appendix comes off, as a rule, from the inner side of the posterior wall of the caecum that is below and behind the termination of the ileum. This origin usually corresponds to **McBurney's point,** which is in the abdominal wall, midway between the umbilicus and the anterior superior iliac spine and which is the usual seat of the greatest tenderness in appendicitis. The origin of the appendix varies with the type of caecum present. These variations are shown in Fig. 913. In the **foetal** or **infantile type** of appendix it arises from the apex of the caecum; in the second type of caecum it arises between the two caecal sacculi; in the third type it arises between a large outer and a small inner sacculus; and on the posterior wall of the caecum, the excessive growth of the anterior wall having caused the appendix to originate posteriorly; in the fourth type there is no internal sacculus, and the appendix arises from the posterior caecal wall behind the ileo-caecal junction (p. 1302). The movable portion of the appendix may be met with in different situations. It may pass upward and in front of the caecum and colon, upward and behind the caecum, and even behind the colon between the two layers of the mesocolon; upward and to the inner side, or upward and to the outer side of the caecum and colon. It may pass to the left under the ileum and mesentery, upward and to the left or downward and to the left into the true pelvis. It may pass directly downward under the caecum. It may pass to the right in front of or back of the caecum. It may occupy any one of the caecal fossae (p. 1262), but most often enters the ileo-caecal fossa. In unusual cases the appendix is found in the inguinal canal as a portion of or the sole contents of a hernia; adherent to the parietal peritoneum in front of or to the side of the caecum, or "behind the peritoneum, below the caecum, adherent to the under surface of the caecum and in contact with its muscular wall and covered by its peritoneal coat."[2] When the caecum is mobile the appendix may be found almost anywhere within the abdomen. When the caecum is undescended the appendix, of course, shares in the failure to descend, and may be below the gall-bladder or in front of the right kidney, and may pass in several directions: upward behind the caecum; to the left behind the ileum and mesentery; or downward and inward into the true pelvis. It varies from one-half an inch to nine inches in length, its average being about three inches. Its diameter is from one-eighth inch to one-quarter inch. The operating surgeon may occasionally fail to find an appendix buried in one of the caecal fossae, and may conclude that the diverticulum is absent. As a matter of fact, unless the colon is also absent, it seems doubtful if the appendix is ever absent, except as a result of dis-

[1] Cunningham's Text-book of Anatomy.
[2] Deaver's Surgical Anatomy.

ease. This view is maintained by Lockwood and Rolleston,[1] by Kelynack,[2] and others. It is asserted by some that the appendix is absent five times out of 10,000 autopsies. It is retained in position by a fold of peritoneum derived from the left leaf of the mesentery, which forms a mesentery for it, and is called the **meso-appendix** (p. 1260), and Figs. 866, 867, and 868). In color the healthy appendix is yellowish-pink, is soft and smooth to the touch, and the "subperitoneal vessels are barely visible."[3] The **canal of the appendix** is small and extends throughout the whole length of the tube. The walls of the healthy diverticulum are thick, and the diameter of the lumen is usually trivial as compared with the diameter of the appendix itself. The lumen of the appendix communicates with the caecum by an orifice which is placed below and behind the ileo-caecal opening (Fig. 919). It is sometimes guarded above and to the left side by a semilunar fold of mucous membrane, the **valve of Gerlach** (*valvula processus vermiformis*). The valve is inconstant, and is never perfect. It is stated that the appendix tends to undergo obliteration as an involution change in a functionless organ. The lumen rarely contains foreign bodies after death, but often contains fecal concretions. Certain it is that in 25 per cent. of necropsies upon adults or elderly people the lumen is found to be partially or completely occluded.

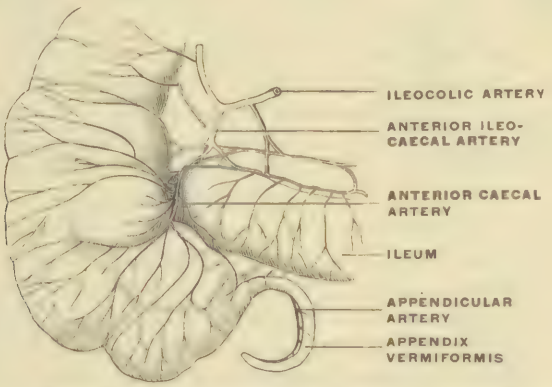

FIG. 914.—Arteries of the cæcum and of the appendix vermiformis and of the terminal portion of the ileum. (Poirier and Charpy.)

Structure of the Appendix (Fig. 917). —The coats of the appendix correspond to the coats of the bowel: **serous, muscular** (the outer layer of longitudinal, the inner of circular fibres), **submucous,** and **mucous.** In the deepest portion of the mucous coat, against the submucous coat, are the unstriated fibres constituting the **muscularis mucosae.** The muscularis mucosae is often present in some regions and absent in others. It may not be present at all.

The **Outer** or **Serous Coat** usually completely covers the appendix and has a definite mesentery, the mesoappendix (p. 1260). Occasionally the base of the appendix is not surrounded by peritoneum, but is extraperitoneal, lying in the retroperitoneal tissue. The **appendiculo-ovarian ligament of Clado** is occasionally present in females. It is a prolongation of the mesoappendix which passes into the broad ligament, and is extremely thin, and its fine connective-tissue fibres send prolongations into the longitudinal muscle-fibres of the appendix. Lockwood points out that the subperitoneal tissue of the meso-appendix and "the blood-vessels, nerves, and lymphatics which it contains are very intimately connected with the submucosa. This union takes place at certain large gaps in the muscular coats. These gaps serve for the transmission of blood-vessels, nerves,

[1] Journal of Anatomy and Physiology, 1891, vol. xxvi.
[2] A Contribution to the Pathology of the Vermiform Appendix.
[3] Lockwood on Appendicitis.

and lymphatics from the mesoappendix to the mucous coat. They are situated at the junction of the mesoappendix with the appendix."[1]

The **Longitudinal Muscular Layer** is thin and irregularly distributed, and in certain regions may be excessively thin or actually absent, and between the fibres are the blood-vessels, nerves, and lymphatics passing from the subperitoneal tissue to the mucous coat.

The **Circular Fibres** are much better developed than the longitudinal fibres, and, according to Lockwood, the layer is 1 mm. thick. Large gaps are found here and there for the passage of vessels, lymphatics, and nerves to and from the mesoappendix and the mucous membrane, and a few vessels pierce the fibres at other points (Lockwood).

The **Submucous Coat** varies greatly in thickness. It contains blood-vessels, nerves, and lymphatics, and some lymphoid follicles.

The **Mucous Membrane** (Fig. 915) is covered by columnar epithelial cells and contains numerous solitary lymph-follicles, some glands of Lieberkühn, surrounded by lymphoid tissue, blood-vessels, lymphatics, and nerves.

The muscularis mucosae may be absent, may be scanty or may be distinct. The **lymphoid follicles** are visible to the naked eye (Fig. 915). Some of them are in the submucosa, some of them chiefly in the mucosa, the bases of the latter, however, being in the submucosa. Lockwood estimates that an appendix three and a half inches in length contains from 150 to 200 follicles.

FIG. 915. The internal surface of the vermiform appendix. (Bonamy and Broca.)

Blood-vessels of the Caecum and Appendix (Figs. 914, 916, 932, and 933).—The **ileo-colic artery** in the ileo-colic angle gives off the **anterior** and **posterior ileo-caecal arteries**. The anterior ileo-caecal runs down over the front of the ileum and supplies the ileum, and sends off a terminal branch, the **anterior caecal artery**, which supplies the anterior surface of the caecum and of a portion of the ascending colon, and to the upper and lower margins of the ileo-caecal valve. It sends no branch to the appendix. The arteries of the appendix come from the **posterior ileo-caecal artery**. This vessel, after arising from the ileo-colic artery, passes back of the termination of the ileum and gives branches to the lower end of the ileum back of a portion of the ascending colon and to the lower margin of the ileo-caecal valve, where they anastomose with the valvular branches from the anterior ileo-caecal (Lockwood). From the posterior ileo-caecal comes the posterior caecal branch, which passes over the posterior and inner portion of the caecum near the base of the appendix and sends one or two branches to the appendix. The chief blood-supply of the appendix is the **appendicular artery**, which comes off the beginning of the posterior ileo-caecal or, occasionally, from the termination of the ileo-colic. If there is a distinct mesoappendix the largest branch of the artery passes along its free edge. If the mesoappendix is absent or rudimentary the artery usually lies upon the appendix from base to tip beneath the peritoneum.

Lockwood points out that the appendicular artery as it enters the mesoappendix divides into three branches. The largest branch runs along the free edge, and from this the tip of the appendix obtains its blood-supply; "the other two reach the appendix at intervals of half an inch."[2] When the branches reach the appendix they divide and pass around it in the subperitoneal coat and send

[1] Appendicitis, its Pathology and Surgery. By Charles Barrett Lockwood.

[2] Ibid.

branches through the muscular gaps to enter and pass through the submucous coat.

In females there is occasionally some additional blood-supply through a branch of the **ovarian artery** in the appendiculo-ovarian ligament.

The **veins** of the appendix are numerous, thin walled, and large. Veins from the submucous plexus pass through the muscular gaps and enter the subperi-

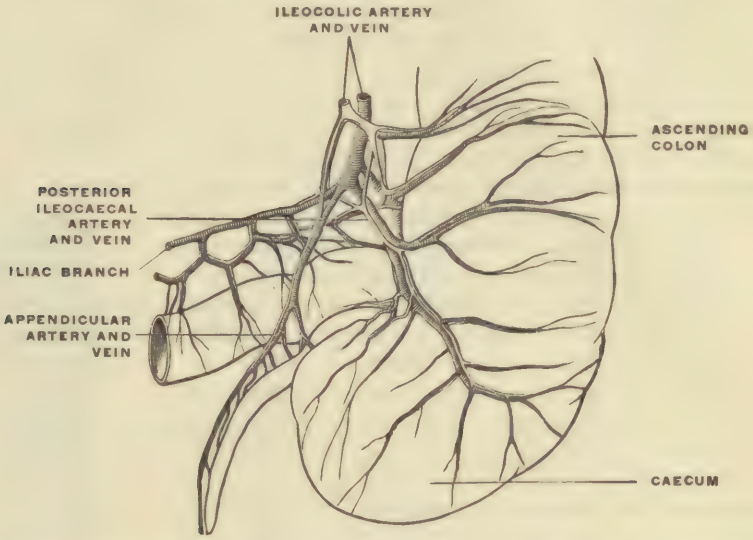

FIG. 916.—Arteries and veins of the cæcum and vermiform appendix seen from behind. (Poirier and Charpy.)

toneal plexus. Veins from the subperitoneal plexus pass into veins in the mesoappendix which correspond to but do not really accompany the arteries (Lockwood). Most of the veins of the mesoappendix pass to the **posterior ileo-caecal vein**, though some pass directly to the **caecal vein**. These veins are radicles of the portal system.

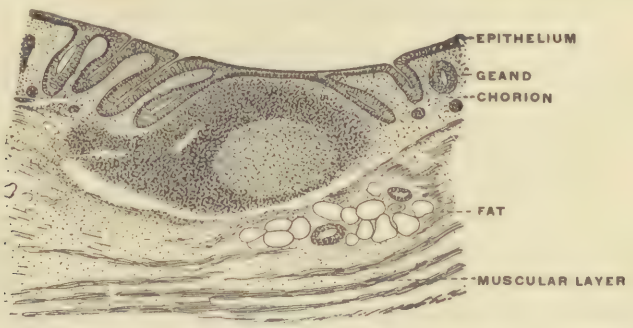

FIG. 917.—Transverse section of the vermiform appendix of man. (Kölliker.)

Lymphatic System of the Caecum and Appendix (Fig. 918).—Surrounding the base of each lymph-follicle in the submucous tissue of the appendix is a lymph-space, which Lockwood calls the **follicular** or **basilar lymph-sinus**. This sinus communicates with the lymphatics of the submucous coat, "which again communicate freely through the hiatus muscularis with those of the peritoneum and of the mesoappendix."[1] The collecting trunks from the caecum and appendix follow the

[1] Appendicitis, its Pathology and Surgery. By Charles Barrett Lockwood.

blood-vessels (Fig. 918). The anterior collecting trunks of the caecum pass through several small glands in the anterior ileo-caecal fold, and terminate in

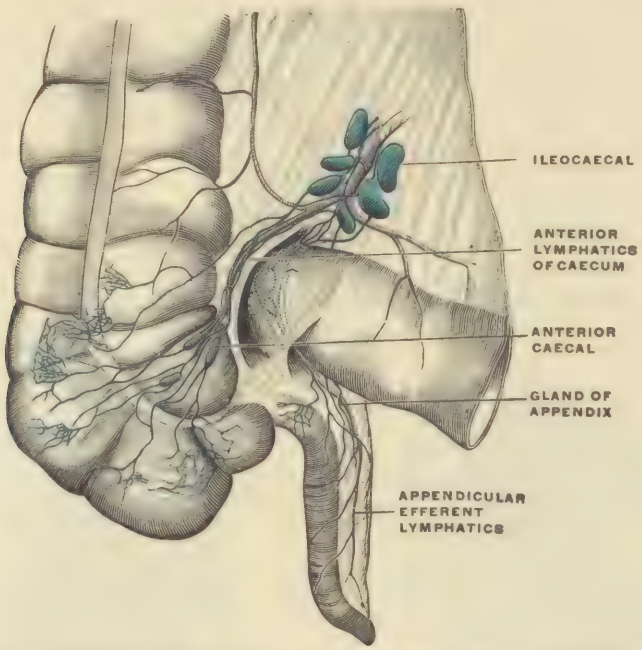

FIG. 918.—Lymphatics of the caecum and appendix, anterior view. (Poirier and Charpy.)

glands along the ileo-colic artery (Fig. 918). The posterior collecting trunks pass through some small glands and terminate in glands along the ileo-colic artery. The appendicular collecting trunks enter the mesoappendix. There are usually four of them, sometimes five. Some of them traverse a gland constantly present at the ileo-caecal angle (Clado). Another gland is constant. It is situated beneath the ileo-colic fossa (Lockwood and Rolleston). The

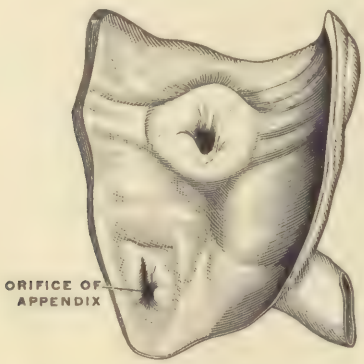

FIG. 919.—Ileo-caecal valve of the circular type. (Poirier.)

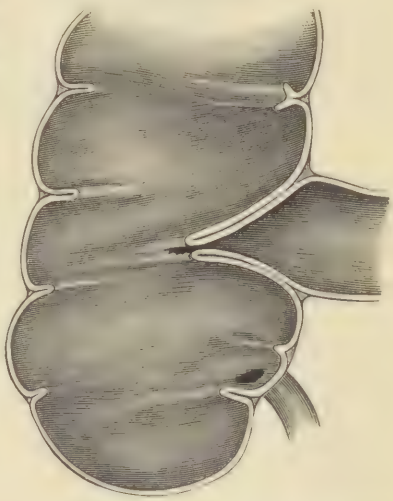

FIG. 920.—Vertical section through the caecum and ileo-caecal valve. (Gegenbauer.)

editor subscribes to Lockwood's statement that in appendicitis there is often a chain of inflamed glands along the inner side of the ascending colon behind the

ascending mesocolon. Hence this is one road taken by the lymphatics of the appendix. The others pass to the mesenteric glands.

The Ileo-caecal Valve or the Valve of Bauhin (*valvula coli*) (Figs. 919, 920, 921, and 922).—The lower end of the ileum terminates by opening into the inner and back part of the large intestine, at the point of junction of the caecum with the colon. The opening is guarded by a valve, consisting of two semilunar segments, an **upper** or **colic segment** (*labium superius*) and a **lower** or **caecal segment** (*labium inferius*), which project into the lumen of the large intestine. The upper one, nearly horizontal in direction, is attached by its convex border to the point of junction of the ileum with the colon; the lower segment, which is more concave and longer, is attached to the point of junction of the ileum with the caecum. At each end of the aperture the two segments of the valve coalesce, and are continued as a narrow membranous ridge around the canal for a short distance. Each **ridge** is known as the **retinaculum** or **frenulum of the valve** (*frenulum valvulae coli*). The left or anterior end of the aperture is rounded; the right or posterior is narrow

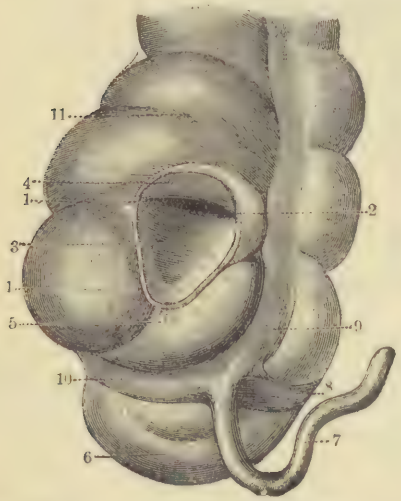

FIG. 921.—Cæcum and vermiform appendix. 1, ileum; 2, orifice of valve; 3, inferior segment; 4, superior segment; 5, long muscular fibres from ileum; 6, cul-de-sac of caecum; 7, appendix; 8, posterior taenia; 9, internal taenia; 10, anterior taenia; 11, sacculus. (Sappey.)

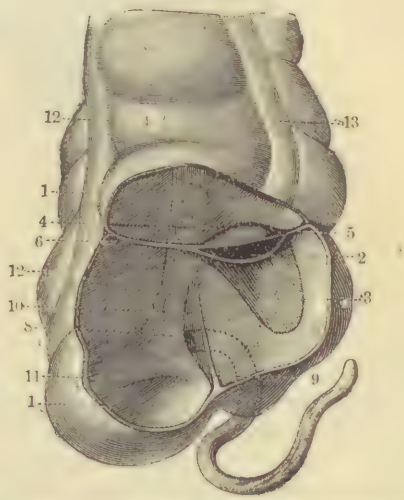

FIG. 922.—Ileo-caecal valve. 1, edge of caecum; 2, orifice of valve; 3, inferior segment; 4, superior segment; 5 and 6, fraena; 7, appendix; 8, mouth; 9, semilunar fold; 10, posterior taenia; 11, 12, 12, anterior taenia; 13, internal taenia. (Sappey.)

and pointed. In the formation of the valve the termination of the small intestine invaginates for a short distance into the lumen of the large intestine (Fig. 920), the invaginated portion of the wall of the small intestine uniting with a corresponding portion of the wall of the large intestine.

Each segment of the valve is formed by a reduplication of the mucous membrane and of the circular muscular fibres of the intestine, the longitudinal fibres and peritoneum being continued uninterruptedly across from one portion of the intestine to the other. When the longitudinal fibres and peritoneum are divided or removed, the ileum may be drawn outward, and all traces of the valve will be lost, the ileum appearing to open into the large intestine by a funnel-shaped orifice of large size.

The surface of each segment of the valve directed toward the ileum possesses villi, and presents the characteristic structure of the mucous membrane of the small intestine; while that turned toward the large intestine is destitute of villi, and marked with the orifices of the numerous tubular glands peculiar to the mucous membrane of the large intestine. These differences in structure continue

as far as the free margins of the valve. When the caecum is distended it is supposed that the margins of the opening are approximated so as to prevent reflux into the ileum. It is known, however, that a very large enema which distends the caecum and colon may in part enter the ileum, being driven there by waves of reversed peristalsis. The valve resists, but a certain amount of pressure overcomes it. Some believe that the so-called ileo-caecal valve is not a valve, but a distinct sphincter. This has been demonstrated to be true in cats and dogs, but lacks demonstration in man (p. 1323).

The Colon.

The colon is divided into four parts—the **ascending, transverse** and **descending colon,** and the **sigmoid flexure.**

The Ascending Colon (*colon ascendens*).—The ascending colon is smaller than the caecum, with which it is continuous. It passes upward, from its commencement at the frenula of the caecum, opposite the ileo-caecal valve, to the under surface of the right lobe of the liver, on the right of the gall-bladder, where it is lodged in a shallow depression on the liver, the **impressio colica**; here it bends abruptly inward to the left, forming the **hepatic flexure** (*flexura coli dextra*). It is retained in contact with the posterior wall of the abdomen by the peritoneum, which covers its anterior surface and sides, its posterior surface being connected by loose areolar tissue with the Quadratus lumborum and Transversalis muscles, and with the front of the lower and outer part of the right kidney (Fig. 923). Sometimes the peritoneum almost completely invests it, and forms a distinct but short mesocolon[1] (p. 1259). It is in relation, in front, with the convolutions of the ileum and the abdominal parietes.

The Transverse Colon (*colon transversum*) (Fig. 858).—The transverse colon, the longest part of the large intestine, passes transversely from right to left across the abdomen, opposite the confines of the epigastric and umbilical zones, into the left hypochondriac region, where it curves downward beneath the lower end of the spleen, forming the **splenic flexure** (*flexura coli sinistra*). In its course the transverse colon describes an arch, the concavity of which is directed backward toward the vertebral column and a little upward; hence the name **transverse arch of the colon.** This is the most movable part of the colon, being almost completely invested by peritoneum, and connected to the spine behind by a large and wide duplicature of that membrane, the **transverse mesocolon** (Fig. 863). The transverse colon is in relation, by its upper surface with the liver and gall-bladder, the great curvature of the stomach, and the lower end of the spleen; by its under surface, with the small intestines; by its anterior surface, with the anterior layers of the great omentum and the abdominal parietes; its posterior surface on the right side is in relation with the second portion of the duodenum, and on the left side is in contact with some of the convolutions of the jejunum and ileum.

The Descending Colon (*colon descendens*).—The descending colon passes downward through the left hypochondriac and lumbar regions along the outer border of the left kidney. At the lower end of the kidney it turns inward toward the outer border of the Psoas muscle, along which it descends to the crest of the ilium, where it terminates in the sigmoid flexure. At its commencement it is connected with the Diaphragm by a fold of peritoneum, the **phreno-colic ligament** (see p. 1259). It is retained in position by the peritoneum, which covers its

[1] Treves states that after a careful examination of one hundred subjects, he found that in fifty-two there was neither an ascending nor a descending mesocolon. In twenty-two there was a descending mesocolon, but no trace of a corresponding fold on the other side. In fourteen subjects there was a mesocolon to both the ascending and the descending segments of the bowel; while in the remaining twelve there was an ascending mesocolon, but no corresponding fold on the left side. It follows, therefore, that in performing lumbar colostomy a mesocolon may be expected on the left side in 36 per cent. of all cases, and on the right in 26 per cent. (The Anatomy of the Intestinal Canal and Peritoneum in Man, 1885, p. 55.)—Ed. of 15th English edition.

anterior surface and sides, its posterior surface being connected by areolar tissue with the outer border of the left kidney, and the Quadratus lumborum and

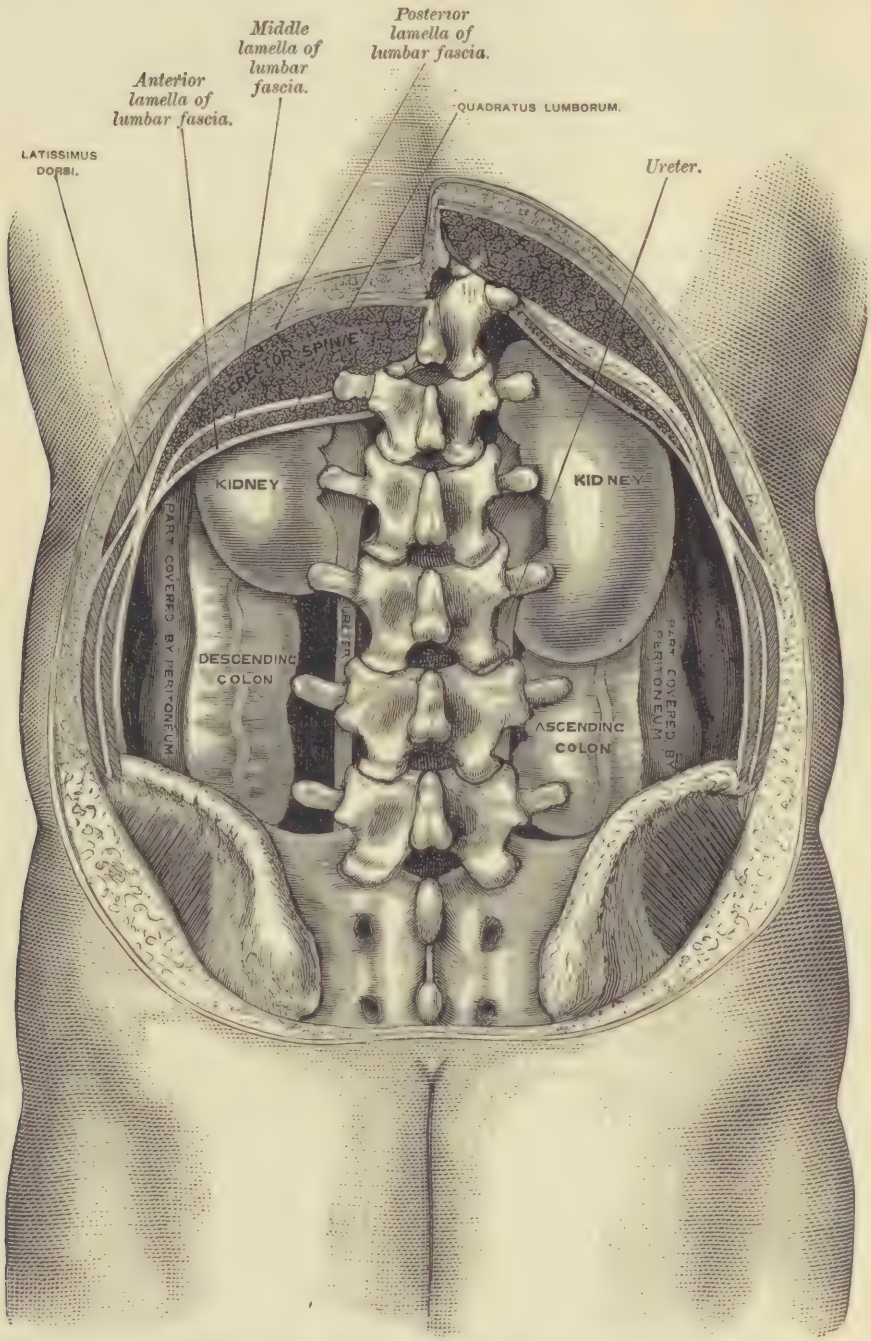

Fig. 923.—Diagram of the relations of the large intestine and kidneys, from behind.

Transversalis muscles (Fig. 863). It is smaller in calibre and more deeply placed than the ascending colon, and is more frequently covered with peritoneum on its posterior surface than the ascending colon (Treves).

The **Sigmoid Flexure, Pelvic Colon** or **Sigmoid Colon** (*colon sigmoideum*) (Figs. 924, 925, 926, and 927) is the narrowest part of the colon; it is situated in the left iliac fossa, commencing from the termination of the descending colon, at the margin of the crest of the ilium, and then forming a loop, which varies in length and position, and which terminates in the rectum at the level of the attachment of the mesentery upon the front of the third sacral vertebra. It passes downward about two inches parallel to the outer border of the Psoas muscle, then taking a transverse direction enters the cavity of the pelvis, crosses this cavity from left to right and a little upward to the lower margin of the right iliac fossa; "from this point it passes downward, backward, and inward along the anterior surface of the sacrum to its junction with the rectum."[1] It is surrounded with the peritoneum and is attached to the poste-

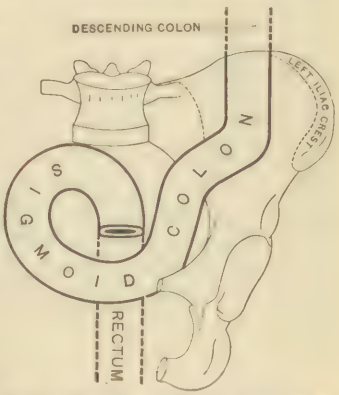

FIG. 924.—Sigmoid colon, front view. Semidiagrammatic. (Testut.)

rior abdominal wall by the **mesosigmoid**, a continuation of the mesocolon, but which greatly exceeds the latter in length, hence the sigmoid is the most mobile

[1] Tuttle, Diseases of the Anus, Rectum, and Pelvic Colon.

portion of the large intestine. Tuttle divides the sigmoid into four portions. The **first** or **vertical portion**; the **second** or **transverse portion**; the **third portion**, which is a loop and is concave upward if the sigmoid occupies the pelvis, and is concave downward if it occupies the abdomen; the **fourth portion**, which is curved irregularly in the hollow of the sacrum, and which joins the rectum as often from the right as from the left. When the sigmoid is lifted up and to the right and the mesosigmoid is put slightly upon the stretch, an opening is seen at the parietal border of the left layer of the mesosigmoid. This opening leads into a *cul-de-sac*, the **intersigmoid fossa**. When the sigmoid is empty most of it falls into the recto-vesical or recto-vaginal space (Fig. 925). When distended it mounts up into the abdomen, reaching to or even above the umbilicus. The sigmoid flexure is in relation in front with the small intestine and abdominal parietes. The sigmoid mesocolon is attached to a line running downward and inward from the crest of the ilium, across the Psoas muscle (Fig. 863).

The Rectum (**Intestinum Rectum**) (Figs. 924, 925, 926, 927, 928, 929).

The rectum is the terminal part of the large intestine, and extends from the termination of the sigmoid flexure to the level of the semilunar valves of Mor-

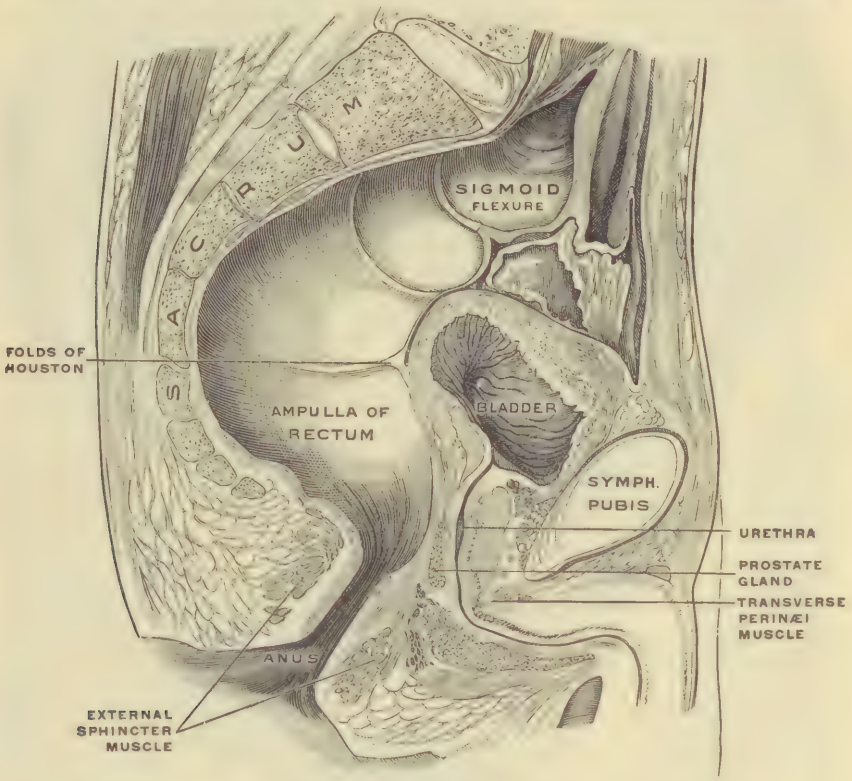

FIG. 926.—Sagittal section in the median line of the pelvis. (Poirier and Charpy.)

gagni. The sigmoid flexure terminates at the level of the attachment of the mesentery in front of the third sacral vertebra. This definition is practical and useful. It was suggested by Sir Frederick Treves. "It gives to the organ definite limits; it separates the mobile from the immobile portion of the gut; it marks the line where the course of the blood-supply changes; it indicates the

point where the three longitudinal muscular bands of the colon spread out and become more or less equally distributed around the gut; and, finally, it marks a point at which there is always a decided narrowing in calibre, indicating the juncture of the rectum with the pelvic colon."[1] The old division added to this the so-called **first part of the rectum**, which we consider as part of the sigmoid colon. The rectum is divided into two portions, a **superior** and an **inferior**. The **superior** or **sacrococcygeal portion of the rectum** (*flexura sacralis*) curves downward with the concavity forward and upward in front of the sacrum and coccyx, and is continued as far as the apex of the prostate gland, about an inch in front of the tip of the coccyx. The **inferior** or **prostatic portion** (*flexura perinealis*) begins at this point. The bowel is directed downward and backward, being convex in front, and terminates at the beginning of the anus at the level of the semilunar valves of Morgagni. The **inferior** or **prostatic portion of the rectum** is described by Symington as the **anal canal**.

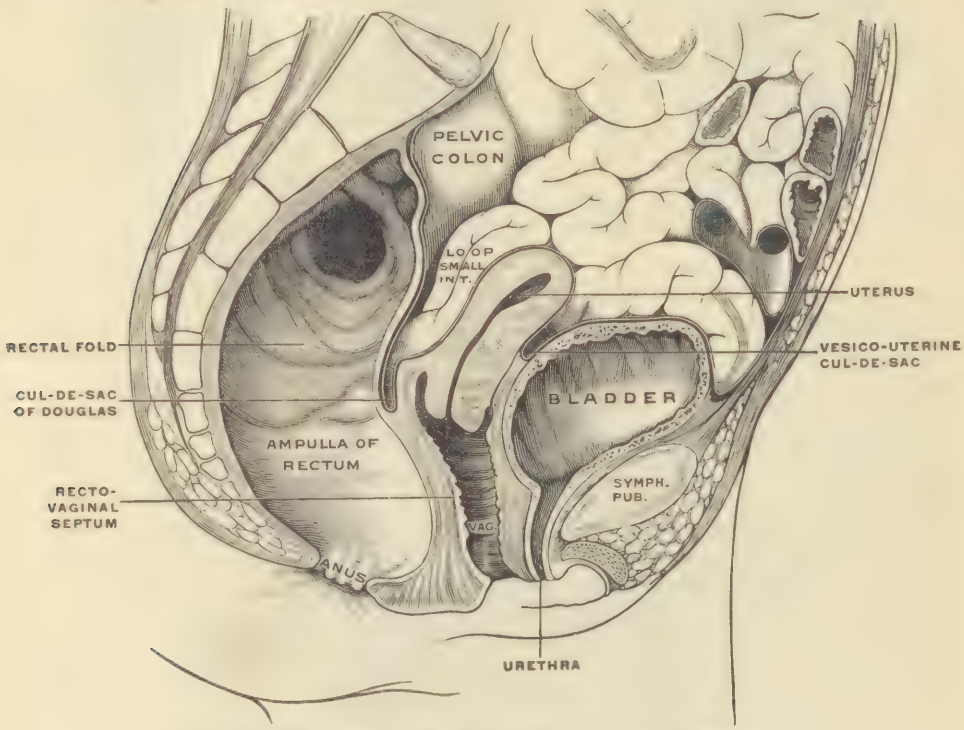

FIG. 927.—Median sagittal section of the female pelvis. (Luschka.)

Curves of the Rectum.—It will be seen, therefore, that the rectum presents two antero-posterior curves: the first, with its convexity backward, is due to the conformation of the sacro-coccygeal column, and represents the arc of a circle, the centre of which is opposite the third sacral vertebra. The lower one has its convexity forward, and is angular. Its centre corresponds to a line drawn between the anterior parts of the ischial tuberosities. Two lateral curves are also described: the one to the right, opposite the junction of the third and fourth sacral vertebrae; the other to the left, opposite the sacro-coccygeal articulation. They are of little importance.

The adult rectum as here described has a length of from four to six inches in men, and from three and five-eighths to five and one-eighth inches in women. According to Tuttle the length of the rectum depends to some degree on the size of the

[1] A Treatise on Diseases of the Anus, Rectum, and Pelvic Colon. By James P. Tuttle.

subject, and is somewhat greater in the old than in the young. The prostatic portion is the narrowest portion of the rectum. The widest part of the rectum is the **ampulla recti** just above the anal canal (Figs. 926 and 927). The prostatic portion has no peritoneal investment whatever and includes the lower two inches of the superior portion of the rectum. When the rectum is empty it is a mere slit, the anterior and posterior walls being in contact. When distended it is "irregularly cylindrical" (Tuttle). At and above the level of the third sacral vertebra the gut is entirely surrounded by peritoneum, and there is a mesosigmoid. This is the mesorectum of those who describe the lower pelvic colon as the first part of the rectum. At the level of the third sacral vertebra the true rectum begins, and the true rectum has no mesorectum. The rectum is covered in front and laterally by peritoneum at its upper part; gradually the peritoneum leaves its sides, and about an inch above the prostate is reflected from the anterior surface of the bowel on to the posterior wall of the bladder in the male, and the upper fifth of the posterior wall of the vagina in the female, forming the **recto-vesical** or **recto-vaginal pouche** (*excavatio rectovesicalis* and *excavatio rectouterina*), as the case may be (Fig. 853). The balance of the rectum has no peritoneal covering. The level at which the peritoneum leaves the anterior wall of the rectum to be reflected on to the viscus in front of it is of considerable importance from a surgical point of view, in connection with removal of the lower part of the rectum. It is higher in the male than in the female. In the former the height of the recto-vesical pouch is about three inches; that is to say, the height to which an ordinary index finger can reach from the anus. In the female the height of the recto-vaginal pouch is about two and a quarter inches from the anal orifice.

Fig. 928. Diagram of rectum, showing Houston's valves in the interior. (Cunningham.)

The upper or sacro-coccygeal portion of the rectum is in relation, in front, in the male, with the recto-vesical pouch, the triangular portion of the base of the bladder, the vesiculae seminales, and vasa deferentia, and more anteriorly with the under surface of the prostate. In the female, with the posterior wall of the vagina below, and the recto-vaginal pouch above, in which are some convolutions of the small intestine (Fig. 927). To the sides below the peritoneal reflections, the rectum is surrounded by cellular tissue in which on each side lie the lateral sacral artery and the bifurcated hypogastric plexus. This portion of the rectum is separated from the sacrum and coccyx by an interval, the **retro-rectal space**, which is filled with cellular tissue. The superior portion of the distended rectum is in contact posteriorly and on each side with the sacral plexus, ganglia of the sympathetic, and the fascial origin of the pyramidalis muscle (Tuttle). The lower or prostatic portion in men is in relation anteriorly with the prostate gland and the membranous urethra; in women with the posterior wall of the vagina. The lower end of the rectum takes a backward turn, and the uro-genital organs turn forward; the intervening space is called the **perineum**. In the female, the fibro-fatty and muscular tissue which occupies this space is called the **perineal body**. The prostatic portion of the rectum is invested by the Internal sphincter, supported by the Levatores ani muscles, and surrounded at its termination by the External sphincter; in the empty condition it presents the appearance of a longitudinal slit. Posteriorly the lower part of the rectum is in contact with cellular tissue, which separates it from the coccygeal gland and the coccyx.

Supports of the Rectum.—The rectum as it has been described in these pages is a fixed tube. The upper portion of the rectum is supported by "the inferior mesenteric arteries and the fibrous sheaths which surround them" (Tuttle); by the peritoneal folds which attach it to the sacrum; and by the peritoneal folds which pass in front to the bladder (*plicae rectovesicales*), or to the uterus (*plicae rectouterinae*), and laterally to the pelvis. The middle of the rectum receives some support from the lateral sacral arteries and their fibrous sheaths. The lower portion of the rectum is supported by the Levator ani, External sphincter, and Recto-coccygeus muscles.

Blood-vessels and Lymphatics of Rectum.—See pp. 1320 and 1322.

Nerves of Rectum.—See p. 1322.

Structure of Rectum.—See p. 1316.

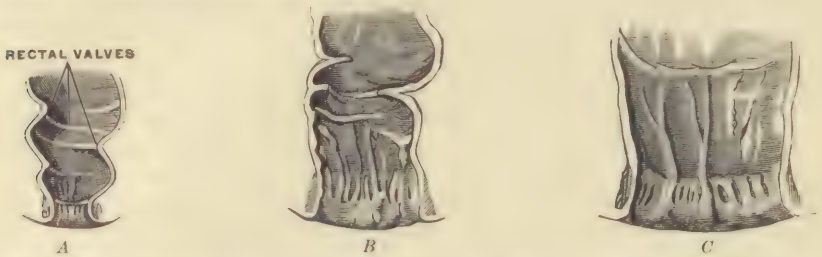

FIG. 929.—The anal canal and lower part of the rectum in the fœtus. *A*, aged four to five months; *B*, six months; *C*, nine months. In each the anal canal is distinctly marked off from the rectum proper; the columns of Morgagni and the rectal valves are distinct. (Cunningham.)

The Common Anal Canal (*pars analis recti*) (Figs. 929 and 930).—The anal canal is the third portion of the rectum of the older descriptions. It begins where the true rectum ends. This canal is the portion of the intestinal tract which

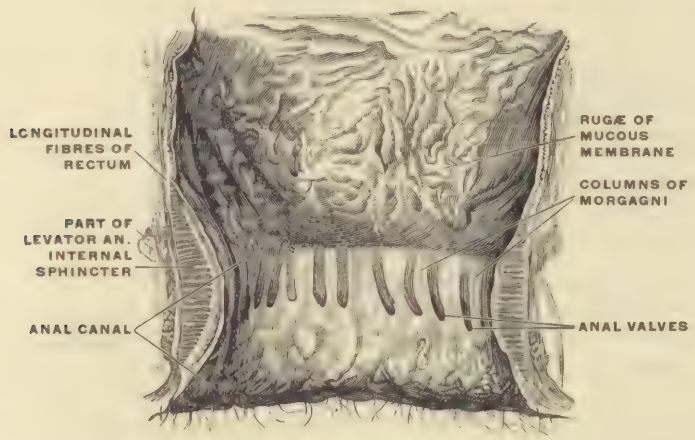

FIG. 930.—The interior of the anal canal and lower part of the rectum, showing the columns of Morgagni and the anal valves between their lower ends. The columns were more numerous in the specimen than usual. (Cunningham.)

is below the distribution of genuine mucous membrane, and is just posterior to the middle of a line drawn from one tuberosity to the other. It lies between the true skin and the upper borders of the semilunar valves of Morgagni. When at rest it is a mere slit placed antero-posteriorly. The external opening of the anal canal is the **anus**. The skin about the anus is pigmented, is thrown into radiating folds by the contraction of the External sphincter muscle, and contains hairs, sebaceous glands, and sudoriparous glands (*glandulae circumanales*). Ascending into the canal, it alters its character and becomes muco-cutaneous,

and true mucous membrane appears at the rectum proper. Back of the anus is a median cutaneous fold passing posterior to the coccyx and called the **anal raphé.** In front of the anus is a median fold which, in the female, passes forward and merges with the labia major and in the male continues into the raphé of the scrotum. This is called the **perineal raphé.** The length of the anal canal is three-quarters to one inch. "Its circumference varies from 3 cm. (one and three-sixteenths inches) in normal condition to 15 cm. (five and five-sixteenths inches) in disease, following injury or vicious practices. The average anus will admit a cylinder of 65 mm. in circumference without rupturing the mucous membrane."[1]

Relations of the Anal Canal.—It is surrounded by the external and internal sphincter muscles, and above by the Levatores ani. To each side is the ischio-rectal fossa containing fat. Between the anal canal and the coccyx is a collection of muscular fibres and connective tissue, the **ano-coccygeal body of Symington.** In front, in the male, is the bulb of the urethra and the base of the triangular ligament; in the female, is the perineal body, which separates the anus from the vagina. There are three layers in the wall of the anal canal:

1. The **muco-cutaneous layer,** which contains glands, blood-vessels, and numererous nerve-endings. The lower portion is covered with pavement-epithelium, but gradually there is a transition, and at the beginning of the rectum proper the epithelium is entirely columnar. The **valves of Morgagni,** the **anal valves** or the **semilunar valves** (Figs. 930 and 931) are in the upper portion of the anal canal between the lower ends of the columns of Morgagni (Figs. 930 and 931). Above the valves the canal is lined by transitional mucous membrane, below them by modified skin.

The ano-rectal line is not straight, but is irregularly dentated by trivial elevations, each of which is papilliform at its summit. According to Tuttle, these elevations number from five to eight. About one-fifth of an inch below the ano-rectal line is the depression known as **Hilton's white line** (*annulus haemorrhoidalis*) (Fig. 931). This line is somewhat indistinct to sight, but can always be felt with the finger. It marks the junction of the External with the Internal sphincter. Above Hilton's line are some mucous crypts and also dilatations produced by the internal haemorrhoidal plexus of veins (Fig. 931).

2. The **fibro-cellular layer** is beneath the mucous membrane. Above Hilton's line it is composed of cellular tissue; below it is a thin fascia-like layer which joins the superficial fascia.

The anal canal is surrounded by longitudinal fibres from the rectum, fibres from the Levator ani, the lower portion of the Internal sphincter, and particularly by the External sphincter.

Blood-vessels, Lymphatics, and Nerves of Anus.—See pp. 1321 and 1322.

Structure of Large Intestine (including the Rectum and Anal Canal).—The large intestine has four coats—**serous, muscular, areolar** or **submucous** and **mucous.**

The Serous Coat (*tunica serosa*).—The serous coat is derived from the peritoneum, and invests the different portions of the large intestine to a variable extent. The caecum is completely covered by the serous membrane, except in a small percentage of cases (5 or 6 per cent.), where a small portion of the upper end of the posterior surface is uncovered. The ascending and descending colon are usually covered only in front and at the sides; a variable amount of the posterior surface is uncovered. The transverse colon is almost completely invested, the parts corresponding to the attachment of the great omentum and transverse mesocolon being alone excepted. The sigmoid flexure is completely surrounded, except along the line to which the sigmoid mesocolon is attached. The upper two-thirds of the rectum is covered in front and laterally by the peritoneum, but not posteriorly, between the two posterior folds of peritoneum, the so-called mesorectum; later

[1] Diseases of the Anus, Rectum, and Pelvic Colon. By James P. Tuttle.

it is covered only on its anterior surface; and the lower portion is entirely devoid of any serous covering. In the course of the colon the peritoneal coat is thrown into a number of small pouches filled with fat, called **appendices epiploicæ**. They are chiefly appended to the transverse colon, and are particularly numerous along the anterior band.

The Muscular Coat (*tunica muscularis*).—The muscular coat consists of an **external longitudinal** and an **internal circular layer** of muscular fibres.

The **Longitudinal Fibres**, although found to a certain extent all around the intestine, do not form a uniform layer over the whole surface of the large intestine. In the caecum and colon they are especially collected into three flat **longitudinal bands** or **taeniae** (*taeniae coli*) (Figs. 910 and 911), each being about half an inch in width. These bands commence at the base of the vermiform appendix, which structure is surrounded by a uniform layer of longitudinal muscular fibres. The bands pass from the base of the appendix to the rectum. At this point they broaden, fuse, and surround the rectum. On the ascending, descending, and sigmoid colon the **mesocolic band** (*taenia mesocolica*) is posterior and internal; the **omental band** (*taenia omentalis*) is posterior and external; the **free band** (*taenia libera*) is anterior. On the transverse colon the taenia libera is inferior; the taenia mesocolica is posterior; the taenia omentalis is anterior and superior. These bands are one-sixth shorter than the other coats of the intestine to which they are applied, and serve to produce the **sacculi** (Fig. 911), which are characteristic of the caecum and colon; accordingly, when they are dissected off, the tube can be lengthened, and its sacculated character becomes lost. The sacculations are called **haustra coli**. There are three rows of the sacculations separated from each other by the longitudinal bands. These pouches are also subdivided by transverse furrows which correspond to concave folds of mucous membrane, called **semilunar folds** (*plicae semilunares coli*). In the sigmoid flexure the longitudinal fibres become more scattered; but upon its lower part, and around the rectum, they spread out and form a layer which completely encircles this portion of the gut, but is thicker on the anterior and posterior surfaces, where two accentuations exist, than on the lateral surfaces. In the rectum the external fibres of the longitudinal layer descend and are inserted into the fascia covering the Levator ani muscle. The middle fibres are mingled with descending fibres of the Levator ani and terminate by attachment to the rectal wall. The internal fibres descend between the External and Internal sphincter muscles and are inserted into the superficial fascia around the anal margin. The lower part of the rectum is surrounded by the Levator ani muscle (p. 451). In addition to the muscular fibres of the bowels, two bands of plain muscular tissue are to be noted. They arise from the front of the second and third coccygeal vertebrae, and pass downward and forward to blend with the longitudinal muscular fibres on the posterior wall of the rectum. Each is known as the **rectococcygeal muscle** (*m. rectococcygeus*).

The **Circular Fibres** form a thin layer over the caecum and colon, being especially accumulated in the intervals between the sacculi. In the rectum the circular fibres constitute a thick coat at some portions of the circumference and a thinner coat at others. The circular fibres are thickened at every flexure. The thickenings only partly surround the gut, and hence are not to be considered as additional sphincters. Tuttle calls them the **semicircular muscles of the rectum**. These semicircular muscles are opposite the insertion of Houston's valves. At the lower end of the rectum the circular fibres become very numerous and constitute the **Internal sphincter muscle** (*m. sphincter ani internus*) (Fig. 930). Tuttle describes it as follows: "This muscle, composed of an aggregation of circular fibres, begins about 4 cm. above the anal margin, and gradually increases in thickness until it reaches the ano-rectal line, after which it thins out again and disappears about the middle

of the anal canal. Its width from above downward averages 1 to 3 cm. (three-fifths of an inch to one and one-fifth inches). Its thickness is so variable that no accurate measurement can be given. Its lower fibres are below and within the grasp of the External sphincter, from which it is separated by a narrow zone of connective tissue. A depressed zone, not always perceptible to the eye, but appreciable by digital touch, marks the line of division between these two muscles."[1] The Internal sphincter is an involuntary muscle. The external sphincter muscle is not a portion of the wall of the bowel. It is described on pages 450 and 451.

The Areolar Coat or Submucous Coat (*tela submucosa*).—The areolar or submucous coat connects the muscular and mucous layers closely together. This coat is thicker, looser, and more elastic in the rectum than elsewhere. In this coat are the blood-vessels, nerves, and lymphatics.

The Mucous Membrane (*tunica mucosa*).—The mucous membrane, in the caecum and colon, is pale, smooth, destitute of villi, and raised into numerous crescentic folds which correspond to the intervals between the sacculi. In the rectum it is thicker, of a darker color, more vascular, and connected loosely to the muscular coat, as in the oesophagus.

The rectum contains certain horizontal folds. Most of them disappear when the gut is distended, but some of them do not disappear, but remain as distinct

FIG. 931.—Inner wall of the lower end of the rectum and anus. On the right the mucous membrane has been removed to show the dilatation of the veins and how they pass through the muscular wall to anastomose with the external haemorrhoidal plexus. (Luschka.)

folds with free crescentic edges. These permanent folds were first described by Houston, of Dublin, and are known as **rectal valves** or **Houston's valves** (*plicae transversales recti*) (Figs. 928 and 929). Each fold surrounds more than one-third of the gut, and is composed of mucous membrane, submucous tissue, and a layer from the circular muscular layer of the gut. There may be three, four, or five of these folds. Three of them are constant. One is on the right rectal wall, about the point of peritoneal reflection; another is on the left side, about one inch above the margin of the anal canal. A third is on the rectal wall, either toward the right or left, at the point where the rectum joins the front of the sigmoid. These shelf-like valves are not perfectly flat, for on the superior surface of each is a depression.

The borders of a valve are thinner than its base and are very flexible. These valves support the mass of faeces as it descends, and give to it a rotary motion

[1] Diseases of the Anus, Rectum, and Pelvic Colon. By James P. Tuttle.

(Tuttle). In the lower end of the rectum the mucous membrane forms longitudinal folds known as the **columns of Morgagni** or the **rectal columns** (*columnae rectales* [*Morgagni*]) (Figs. 930 and 931). There are from five to ten of these folds, each of which is about one-half an inch long, and they contain longitudinal muscle-fibres. They are most prominent when the sphincter contracts. The base of each column helps to form the upper margin of the anal canal. The outer angle of each column below passes into a semilunar valve. The grooves between the columns are shallow above and deeper below, and end in the semilunar valves. The **semilunar valves, valves of Morgagni** or **anal valves** (Figs. 930 and 931) are folds which stretch from the base of one column to another, and form the **anal pockets** or **crypts of Morgagni** (*sinus rectales*). These pockets are about 5 mm. in depth. They are most marked posteriorly (Ball), but none exists in either the anterior or posterior commissure (Tuttle). Below the sinuses is the **white line of Hilton** (*annulus haemorrhoidalis*) (Fig. 931), which reaches to the region where hair and sebaceous glands appear.

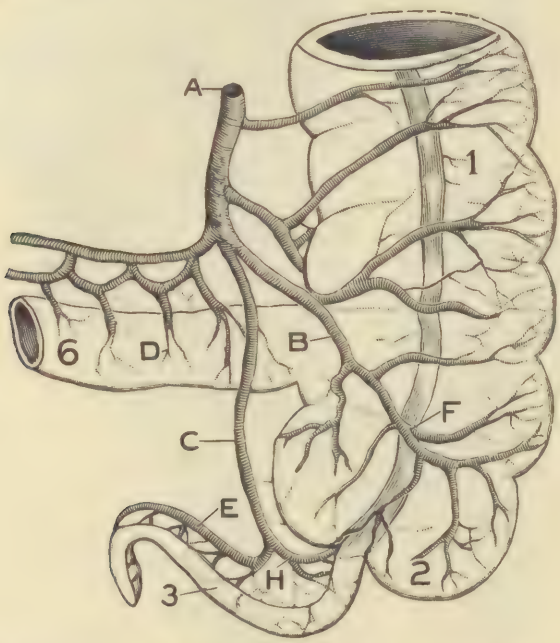

FIG. 932.—The arterial circulation in the dorsal posterior surface of the caecum and appendix. *A*, ileo-colic artery; *B* and *F*, posterior caecal artery; *C*, appendicular artery; *E*, appendicular artery for free end; *H*, artery for basal end of appendix; 1, ascending or right colon; 2, external sacculus of the caecum; 3, appendix; 6, ileum; *D*, arteries on the dorsal surface of the ileum. (Byron Robinson.)

As in the small intestine, the mucous membrane consists of a muscular layer, the **muscularis mucosae** (Fig. 935); of a quantity of retiform tissue in which the vessels ramify; of a basement-membrane and epithelium, which is of the columnar variety, and exactly resembles the epithelium found in the small intestine. In the rectum the epithelial cells are columnar; at the lower end of the tube, however, they begin to change into stratified polyhedrons and prisms. The mucous membrane of the large intestine presents for examination simple **follicles** and **solitary glands**.

The **Simple Follicles, Intestinal Glands, Crypts** or **Glands of Lieberkühn** (*glandulae intestinales* [*Lieberkuhni*]) (Fig. 935) are minute tubular prolongations of the mucous membrane arranged perpendicularly, side by side, over its entire surface; they are longer, more numerous, and are placed in much closer apposition than those of the small intestine; and they open by minute rounded orifices upon the surface, giving it a cribriform appearance.

The **Solitary Glands** (*noduli lymphatici solitarii*) (Fig. 935) in the large intestine are most abundant in the caecum and vermiform appendix, but are irregularly scattered also over the rest of the intestine. They are similar to those of the small intestine.

Vessels of the Large Intestine.—The **arteries** supplying the large intestine give off large branches, which ramify between the muscular coats supplying them, and, after dividing into small vessels in the submucous tissue, pass to the mucous membrane. The caecum, the appendix, and the ileo-caecal valve are supplied by the branches from the anastomotic loops between the **right colic** and **ileo-**

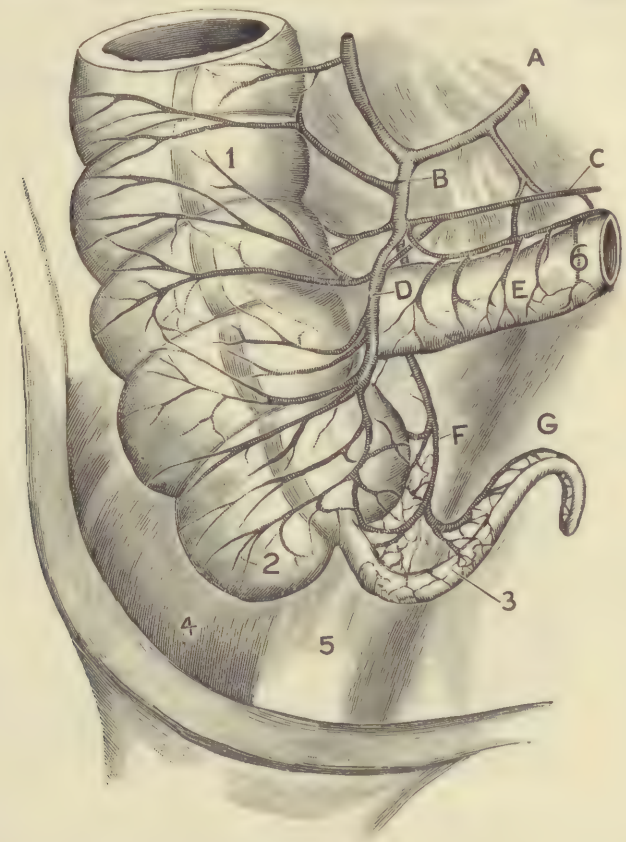

FIG. 933.—The arterial blood-supply of the anterior (ventral) surface of the caecum and appendix. *A*, ileo-colic artery; *B*, caecal-appendicular artery; *D*, anterior caecal artery; *F* and *G*, appendicular artery. Note that the caecal and appendicular arteries anastomose by fine capillaries, both ventral and dorsally; *C*, iliac artery; 1, right colon; 2, external sacculus of caecum (to right of taenium coli); 3, appendix; 4, Iliac, and 5, Psoas muscles. (Byron Robinson.)

colic branches of the superior mesenteric artery (Figs. 932 and 933). In males the sole blood-supply of the appendix is by the appendicular artery from the posterior ileo-caecal branch of the ileo-caecal artery (Fig. 933). In the female the appendix occasionally receives an additional vessel along the appendiculo-ovarian ligament from the ovarian artery. The ascending colon is supplied by the **right colic,** and the transverse colon by the **middle colic branch of the superior mesenteric.** The descending colon is supplied by the **left colic branch of the inferior mesenteric,** and the sigmoid flexure by the **sigmoid branches of the inferior mesenteric.** The rectum (Fig. 934) is supplied mainly by the **superior haemorrhoidal branch of the inferior mesenteric,** but also at its lower end by the **middle haemorrhoidal from the internal iliac,** and the **inferior haemorrhoidal from the pudic artery.** The supe-

rior haemorrhoidal, the continuation of the superior mesenteric, divides into two branches, which run down either side of the rectum to within about five inches of the anus; they here split up into about six branches, which pierce the muscular coat and descend between it and the mucous membrane in a longitudinal direction, parallel with each other as far as the Internal sphincter, where they anastomose with the other haemorrhoidal arteries and form a series of loops around the anus. The **veins** of the large intestine correspond to the arteries and join the **superior** and **inferior mesenteric veins** which join the **portal vein.** The veins of the rectum (Fig. 934) commence in a plexus of vessels which surrounds the lower extremity of the intestinal canal. In the vessels forming this plexus are small saccular dilatations just within the margin of the anus (Figs. 931 and 934); from it about six vessels of considerable size are given off. These ascend between the muscular and mucous coats for about five inches, running parallel to each other; they then pierce the muscular coat, and, by their union, form a single trunk, the **superior haemorrhoidal vein,** which empties into the **inferior mesenteric branch of the portal vein.** This arrangement is termed the **haemorrhoidal plexus** (Fig. 473); it communicates with the tributaries of the middle and inferior haemorrhoidal veins at its commencement, and thus a communication is established between the systemic and portal circulations. The **inferior haemorrhoidal veins** empty into the internal pudic veins, and the **middle haemorrhoidal veins** empty into the internal iliac veins.

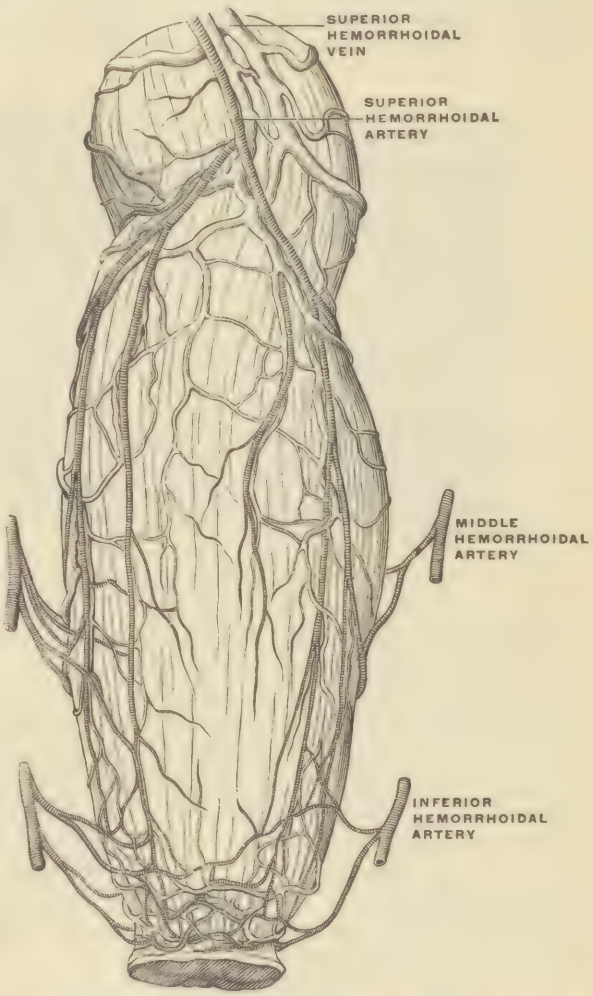

FIG. 934.—The blood-vessels of the rectum and anus, showing the distribution and anastomosis on the posterior surface near the termination of the gut. (Poirier and Charpy.)

The Lymphatics of the Large Intestine.—The lymphatics of the large intestine begin in the mucous membrane and form an extensive plexus in the submucosa. There are also lymphatics more deeply seated, beneath the simple follicles. Those from the ascending colon and transverse colon open into the glands within the mesocolon and behind the colon (mesocolic glands), from which glands trunks pass to the superior mesenteric glands. The lymphatics from the transverse colon join with lymph-vessels of the great omentum, and hence communicate with the lymphatics of the greater curvature of the stomach. The lymph from the descending colon, from the sigmoid and from the pelvic colon passes to

the glands along the inferior mesenteric artery. The lymphatics of the rectum pass first to the rectal glands, which lie on the muscular coat of the rectum, next to the glands which lie back of the rectum along the superior haemorrhoidal artery, and finally to the sacral glands. Lymphatics from the skin of the anus pass with the lymphatics of the skin to the superficial inguinal glands. Lymphatics from the anus between the skin margin and Hilton's white line pass to the hypogastric glands.

The Nerves of the Anus and Rectum.—The **nerves** of the anus and rectum are derived from both the **sympathetic** and **cerebro-spinal system.** The chief supply of the rectum is from the **mesenteric, sacral,** and **hypogastric plexuses of the sympathetic.** It also obtains small branches from the **third, fourth,** and **fifth sacral nerves.** The lower part of the rectum is much more sensitive than the upper part. The muscles of the anus and rectum are supplied "from the intricate plexuses formed by the second, third, fourth, and fifth sacral nerves" (Tuttle). The External sphincter is supplied by nerves which contain motor, sensory, and

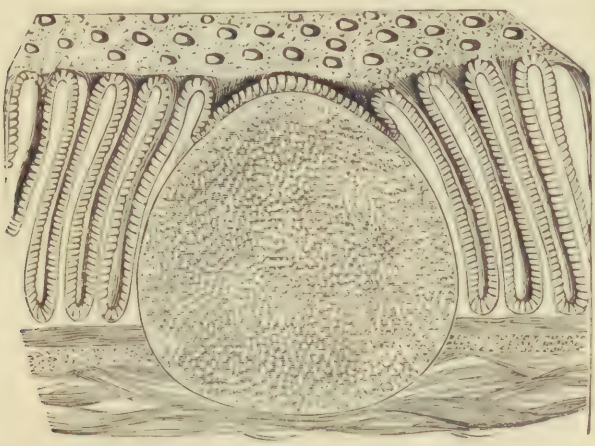

FIG. 935.—Minute structure of large intestine.

sympathetic fibres. These nerves come from three sources. "Two filaments from the branches formed by the third, fourth, and fifth sacral nerves extend transversely across the ischio-rectal fossa and distribute themselves to the middle portion of the muscle and to the peri-anal cutaneous surface; a filament which comes off from the internal pudic just before its division into terminal branches supplies the anterior portion of the muscle, and is called the **anterior sphincterian nerve**; while a filament coming off from the fifth and sixth sacral nerves passes down into the hollow of the sacrum, between the Lævator ani muscle and the recto-coccygeus ligament, and finally reaches the posterior superficial surface of the External sphincter."[1] The spinal centre for the nerves of the anus and rectum is opposite the first lumbar vertebra, and is in practically the same region as the centre for the genito-urinary organs.

Movements and Innervation of the Intestines.

Movements.—As the *small intestine* is devoid of any sphincter arrangement peristalsis cannot mix the food as it does in the pyloric portion of the stomach. The process by which the food is mixed with the secretions and is brought against the intestinal wall for absorption is called by Cannon "rhythmic segmentation." Rhythmic motions, according to Cannon, "mix the

[1] Diseases of the Anus, Rectum, and Pelvic Colon. By James P. Tuttle

food and expose it to the mucosa without advancing it *appreciately* along the canal."[1] In this process constrictions occur in the circular fibres, with the result that a collection of stationary food is divided into a number of segments. In the middle of each segment constrictions appear and the earlier constrictions relax. Then the later constrictions relax and the earlier reappear and so on until the food is thoroughly mixed with digestive secretions. Finally the food is driven on by peristalsis coming again to rest and being again subjected to "rhythmic segmentation."[2] Cannon says that in the duodenum "rhythmic segmentation" lasts for several minutes, but in other parts of the intestine it may continue for half an hour or more, the food which is being subjected to it scarcely moving along the canal. Cannon infers that in man there are from seven to eight segmentations per minute in a given area. It is probable that there is a sphincter action at the ileo-caecal opening.

Cannon divides the large intestine into two parts: a distal part, in which the material is hard and lumpy and is "advanced by rings of tonic contraction," and a proximal part, in which the material is soft. In this part "the common movements are waves of constriction running backward toward the caecum."[3] The resistance of the valve or sphincter enables reversed peristalsis or antiperistalsis to mix the food. When more food enters from the small intestine, antiperistalsis ceases, tonic contraction of the caecum and proximal portion of the colon occurs, some of the food is merged into the transverse colon, and antiperistalsis again begins to act on what remains.[4] The above facts have been observed in animals and are probably true in man.

Innervation.—The pneumogastric fibres of the small intestine seem to excite contraction of the circular fibres after a brief preliminary period of inhibition.[5] Some observers maintain that the splanchnic fibres are inhibitory, but others claim that they are also motor. The local reflex of the small intestine is in Auerbach's plexus. Cannon quotes Bayliss and Starling to the effect that the pelvic visceral nerves to the large intestine, "arising like the vagus from the central nervous system, are augmentary nerves, whereas the supply from the sympathetic system is purely inhibitory in its action."[6] It is further contended that the pelvic visceral nerves are distributed to the distal colon only. "The region of antiperistalsis does not, therefore, receive motor impulses from the pelvic nerves."[7]

Surface Form.—The coils of the small intestine occupy the front of the abdomen below the transverse colon, and are covered more or less completely by the great omentum. For the most part the coils of the jejunum occupy the left side of the abdominal cavity—*i. e.*, the left lumbar and inguinal regions and the left half of the umbilical region—whilst the coils of the ileum are situated to the right, in the right lumbar and inguinal regions, in the right half of the umbilical region, and also in the hypogastric region. The caecum is situated in the right inguinal region. Its position varies slightly, but the mid-point of a line drawn from the anterior superior spinous process of the ilium to the symphysis pubis will about mark the middle of its lower border. It is comparatively superficial. From it the ascending colon passes upward through the right lumbar and hypochondriac regions, and becomes more deeply situated as it ascends to the hepatic flexure, which is deeply placed under cover of the liver. The transverse colon crosses the belly transversely on the confines of the umbilical and epigastric regions, its lower border being on a level slightly above the umbilicus, its upper border just below the greater curvature of the stomach. The splenic flexure of the colon is situated behind the stomach in the left hypochondrium, and is on a higher level than the hepatic flexure. The descending colon is deeply seated, passing down through the left hypochondriac and lumbar regions to the sigmoid flexure, which is situated in the left inguinal region, and which can be felt in thin persons, with relaxed abdominal walls, rolling under the fingers when empty, and when distended forming a distinct bulge. The position of the base of the vermiform appendix is indicated by a point two inches from the anterior superior spinous process of the ilium, on a line drawn from this process to the umbilicus. This is known as *McBurney's point*. Another mode of defining the position of the base of the appendix is to draw a line between the anterior superior spines of the ilia and marking the point where this line intersects the right semilunar line.

Upon introducing the finger into the rectum, the membranous portion of the urethra can be felt, if an instrument has been introduced into the bladder, exactly in the middle line; behind this the prostate gland can be recognized by its shape and hardness and any enlargement detected; behind the prostate the fluctuating wall of the bladder when full can be felt, and if thought desirable it can be tapped in this situation; on either side and behind the prostate the vesiculae seminales can be readily felt, especially if enlarged by tuberculous disease. Behind, the coccyx is to be felt, and on the mucous membrane one or two of Houston's folds. The ischio-rectal fossae can be explored on either side, with a view to ascertaining the presence of deep-seated collections of pus. Finally, it will be noted that the finger is firmly gripped by the sphincter for about an inch up the bowel. By gradual dilatation of the sphincter, the whole hand can be

introduced into the rectum so as to reach the descending colon. This method of exploration is not at the present day employed for diagnostic purposes.

Surgical Anatomy. The small intestine is much exposed to injury, but, in consequence of its elasticity and the ease with which one fold glides over another, it is not so frequently ruptured as would otherwise be the case. Any part of the small intestine may be *ruptured*, but probably the most common situation is the transverse duodenum, on account of its being more fixed than other portions of the bowel, and because it is situated in front of the bodies of the vertebrae, so that if this portion of the intestine is struck a sharp blow, as from the kick of a horse, it is unable to glide out of the way, but is compressed against the bone and lacerated. *Wounds* of the intestine sometimes occur. If the wound is a small puncture, under, it is said, three lines in length, there may be no extravasation of the contents of the bowel. The mucous membrane becomes everted and perhaps plugs the little opening. The bowels, therefore, may be punctured with a fine capillary trocar, in cases of excessive distention of the intestine with gas, without much danger of extravasation. A longitudinal wound gapes more than a transverse wound, owing to the greater thickness of the circular muscular coat. In closing a wound of the intestine, use Lembert's inversion sutures, which bring the peritoneal surfaces in contact. Halsted showed us that these sutures must include the tough submucous coat. The portions of intestine which lie in the pelvis are inflamed in *pelvic peritonitis* and become embedded in adhesions. The portions of intestine which may be present are the termination of the ileum, the portion of small intestine with the largest mesentery (Treves), the rectum, and the pelvic colon. The small intestine, and most frequently the ileum, may become *strangulated* by internal bands, or through apertures, normal or abnormal. The bands may be formed in several different ways: they may be old peritoneal adhesions from previous attacks of peritonitis; or adherent omentum from the same cause; or the band may be formed by *Meckel's diverticulum*, which has contracted adhesions at its distal extremity; or the band may be the result of the abnormal attachment of some normal structure, as the adhesion of two appendices epiploicae, or an adherent vermiform appendix or Fallopian tube. *Intussusception* or invagination of the small intestine may take place in any part of the jejunum and ileum, but the most frequent situation is at the ileo-caecal valve, the valve forming the apex of the entering tube. This form may attain great size, and it is not uncommon in these cases to find the valve projecting from the anus. *Stricture*, the *impaction of foreign bodies*, and twisting of the gut (*volvulus*) may lead to intestinal obstruction. Volvulus is most common in the sigmoid flexure. Meckel's diverticulum may itself become twisted and strangulated.

Resection of a portion of the intestine may be required in cases of gangrenous gut; in cases of intussusception; for the removal of new growth in the bowel; in dealing with artificial anus; and in cases of rupture. The operation is termed *enterectomy*, and is performed as follows: the abdomen having been opened and the amount of bowel requiring removal having been determined upon, the gut must be clamped on either side of this portion in order to prevent the escape of any of the contents of the bowel during the operation. The portion of bowel is then separated above and below by means of scissors. If the portion removed is small, it may be simply removed from the mesentery at its attachment and the bleeding vessels tied; but if it is large, it will be necessary to remove also a triangular piece of the mesentery, and having secured the vessels, suture the cut edges of this structure together. The surgeon then proceeds to unite the cut ends of the bowel together. He may do it by the operation termed *end-to-end anastomosis*. There are many ways of doing this, which may be divided into two classes: one, where the anastomosis is made by means of some mechanical appliance, such as Murphy's button, or one of the forms of decalcified bone bobbins; and the other, where the operation is performed by simply suturing the ends of the bowel in such a manner that the peritoneum covering the free divided ends of the bowel is brought into contact, so that speedy union may ensue.

In some cases after resection each open end of the gut is closed, the side of the terminal portion is sutured to the side of the initial portion, a fistula is made in each, and the suturing is completed so as to cause the two fistulae to correspond. A permanent side-to-side opening is thus made. *Lateral anastomosis* without resection may be practised between two pieces of intestine, in order to side-track an intervening portion, which is the seat of malignant disease or of an artificial anus. *Complete exclusion* of a portion of intestine is performed for irremovable tumors or persistent faecal fistulae of the large intestine. The intestine is cut through above and below the diseased area and the ends of the healthy gut are united to each other, or the larger end is closed, an opening is made into the side of the larger end and the smaller end is implanted in it (*lateral implantation*). The two ends of the excluded portion are fastened to the skin and are left open.

In ascites resulting from cirrhosis of the liver benefit occasionally follows the performance of *Talma's operation* (*epiplopexy*). The abdomen is opened and the omentum is sutured to the anterior abdominal wall or in the abdominal wound in the hope of establishing a more free communication between the portal and systemic circulations, thus lowering portal pressure.

External hernia is considered on page 1325.

By the term *internal hernia*, we mean hernia into the foramen of Winslow, into the retro-

duodenal fossa, into the retro-caecal fossa, or into the intersigmoid fossa. Such a hernia produces the symptoms of acute strangulation of the intestine.

In *typhoid fever* there is ulceration of Peyer's patches. One of these ulcers may *perforate*. The only chance for life is immediate laparotomy and closure of the perforation. This saves one-fifth, or possibly one-third, of the cases. The incision is made to expose the lower ileum, as in the vast majority of cases the perforation is in this portion of the gut.

Ulcer of the duodenum is more common than used to be thought. The portion of the duodenum between the pylorus and the bile papilla is about four inches in length, and is called by the Mayo brothers the *vestibule of the duodenum*. Here the acid gastric juice enters and may produce an ulcer. The portion of the duodenum below the vestibule is not liable to ulcer, because it is protected by the alkaline bile and pancreatic juice.

A duodenal ulcer may perforate a large duodenal vessel and cause death from hemorrhage, or may perforate the intestine and produce septic peritonitis. A perforated ulcer is treated by laparotomy and closure of the perforation. Occasionally ulceration of the duodenal glands (*Curling's ulcer*) may occur in cases of burns, but is not a very common complication.

The vermiform appendix is very liable to become inflamed, the condition being known as *appendicitis*. This condition may be set up by a catarrhal inflammation arising in the appendix or derived from the colon. It may remain catarrhal and then subside. It may become purulent or may be purulent from the beginning. Anything which lessens vital resistance makes the appendix a ready prey to bacteria. Among causes which lessen resistance are fæcal concretions, twists of the mesoappendix cutting off the blood-supply, bruises inflicted by the Psoas muscle (Byron Robinson), blocking of the outlet of the appendix by catarrhal exudate, concretions, proliferated lymphoid tissue, or adhesions. Appendicitis may arise by the appendix becoming twisted, owing to the shortness of its mesentery, in consequence of distention of the caecum. As the result of inflammation, its blood-supply, which is mainly through one large artery running in the mesoappendix, becomes interfered with. Again, in rarer cases, the inflammation is set up by the impaction of a solid mass of fæces or a foreign body in the appendix. The inflammation may result in ulceration and perforation, or in gangrene of the appendix the appendix may be blocked and full of pus, or abscess may form outside of it (*appendicular abscess*). These conditions require prompt operative interference, and in cases of recurrent attacks of appendicitis it is advisable to remove this diverticulum between the attacks. In *external hernia* the ileum is the portion of bowel most frequently herniated. When a part of the large intestine is involved, it is usually the caecum, and this may occur even on the left side. In some few cases the vermiform appendix has been the part implicated in cases of strangulated hernia, and has given rise to serious symptoms of obstruction. The diameter of the large intestine gradually diminishes from the caecum, which has the greatest diameter of any part of the bowel, to the point of junction of the sigmoid flexure with the rectum, at or a little below which point stricture most commonly occurs and diminishes in frequency as one proceeds upward to the caecum. When distended by some *obstruction* low down, the outline of the large intestine can be defined throughout nearly the whole of its course—all, in fact, except the hepatic and splenic flexures, which are more deeply placed; the distention is most obvious in the two flanks and on the front of the abdomen just above the umbilicus. The caecum, however, is that portion of the bowel which is, of all, most distended. It sometimes assumes enormous dimensions, and has been known to give way from the distention, causing fatal peritonitis. The hepatic flexure and the right extremity of the transverse colon are in close relationship with the liver, and abscess of this viscus sometimes bursts into the gut in this situation. The *gall-bladder* may become adherent to the colon, and *gall-stones* may find their way through into the gut, where they may become impacted or may be discharged per anum. The mobility of the sigmoid flexure renders it more liable to become the seat of a *volvulus* or twist than any other part of the intestine. It generally occurs in patients who have been the subjects of habitual constipation, and in whom, therefore, the mesosigmoid is elongated. The gut at this part being loaded with fæces, from its weight falls over the gut below, and so gives rise to the twist.

The surgical anatomy of the rectum is of considerable importance. There may be congenital malformation due to arrest or imperfect development. Thus, there may be no invagination of the epiblast, and consequently a complete absence of the anus; or the hind-gut may be imperfectly developed, and there may be an absence of the rectum, though the anus is developed; or the invagination of the epiblast may not communicate with the termination of the hind-gut from want of solution of continuity in the septum which in early fœtal life exists between the two. The mucous membrane is thick and but loosely connected to the muscular coat beneath and thus favors *prolapse*, especially in children. The vessels of the rectum are arranged as mentioned above, longitudinally, and are contained in the loose cellular tissue between the mucous and muscular coats, and receive no support from surrounding tissues, and this favors varicosity. Moreover, the veins, after running upward in a longitudinal direction for about five inches in the submucous tissue, pierce the muscular coats, and are liable to become constricted at this point by the contraction of the muscular wall of the gut. In addition to this there are no valves in the superior hemorrhoidal veins, and the vessels of the rectum are placed in a depen-

dent position, and are liable to be pressed upon and obstructed by hardened fæces. The anatomical arrangement, therefore, of the hemorrhoidal vessels explains the great tendency to the occurrence of piles. The presence of the Sphincter ani is of surgical importance, since it is the constant contraction of this muscle which prevents an *ischio-rectal abscess* from healing and tends to cause a fistula. Also, the reflex contraction of this muscle is the cause of the severe pain complained of in *fissure of the anus*. The relations of the peritoneum to the rectum are of importance in connection with the operation of removal of the lower end of the rectum for malignant disease. The membrane gradually leaves the rectum as it descends into the pelvis; first leaving its posterior surface, then the sides, and then the anterior surface to become reflected in the male on to the posterior wall of the bladder, forming the recto-vesical pouch, and in the female on to the posterior wall of the vagina, forming Douglas's pouch. The recto-vesical pouch of peritoneum extends to within three inches from the anus, so that it is not desirable to remove more than two and a half inches of the entire circumference of the bowel, for fear of the risk of opening the peritoneum. When, however, the disease is confined to the posterior surface of the rectum, or extends farther in this direction, a greater amount of the posterior wall of the gut may be removed, as the peritoneum does not extend on this surface to a lower level than five inches from the margin of the anus. The recto-vaginal or Douglas's pouch in the female extends somewhat lower than the recto-vesical pouch of the male, and therefore it is advisable to remove a less length of the tube in this sex. Of recent years, however, much more extensive operations have been done for the removal of cancer of the rectum, and in these the peritoneal cavity has necessarily been opened. If, in these cases, the opening is plugged with iodoform gauze until the operation is completed and then the edges of the wound in the peritoneum is accurately brought together with sutures, no evil result appears to follow. For cases of *cancer of the rectum* which are too low to be reached by abdominal section, and too high to be removed by the ordinary operation from below, Kraske has devised an operation which goes by his name. The patient is placed on his right side and an incision is made from the second sacral spine to the anus. The soft parts are now separated from the back of the left side of the sacrum as far as its left margin, and the greater and lesser sacro-sciatic ligaments are divided. A portion of the lateral mass of the sacrum, commencing on the left border at the level of the third posterior sacral foramen, and running downward and inward through the fourth foramen to the cornu, is now cut away with a chisel. The left side of the wound being now forcibly drawn outward, the whole of the rectum is brought into view, and the diseased portion can be removed, leaving the anal portions of the gut, if healthy. The two divided ends of the gut can perhaps then be approximated and sutured together. Kraske's operation is in many cases preceded by the performance of iliac colostomy. In cancer high up in the rectum removal of the growth through the abdomen is sometimes practised, the divided lower end of the rectum being sutured to the divided upper end (Weir's operation).

The colon frequently requires opening in cases of intestinal obstruction, and by some surgeons this operation is performed in cases of cancer of the rectum, as soon as the disease is recognized, in the hope that the rate of growth may be retarded by removing the irritation produced by the passage of fecal matter over the diseased surface. The operation of *colostomy* may be performed either in the inguinal or lumbar region; but *inguinal colostomy* (Maydl's operation) has at the present day superseded the lumbar operation. The main reason for preferring this operation is that a spur-shaped process can be formed which prevents any fecal matter finding its way past the artificial anus and becoming lodged on the diseased structures below. The sigmoid flexure being surrounded by peritoneum, a coil can be drawn out of the wound, and when it is opened transversely a spur is formed, and this prevents any fecal matter finding its way from the gut above the opening into that below. The operation is performed by making an incision two or three inches in length from a point one inch internal to the anterior superior spinous process of the ilium, parallel to Poupart's ligament. The various layers of abdominal muscles are cut through, and the peritoneum opened and sewed to the external skin. The sigmoid flexure is now sought for, and pulled out of the wound and fixed by pushing a glass bar through a slit in the mesocolon. The two parts of the loop are sutured together. The intestine is now sutured to the parietal peritoneum. The wound is dressed, and either immediately or between the second to the fourth day, according to the requirements of the case, the protruded coil of intestine is opened. It is opened transversely with the Paquelin cautery.

THE LIVER (HEPAR) (Figs. 936, 937, 938, 939).

The liver is the largest gland in the body, and is situated in the upper and right part of the abdominal cavity, occupying almost the whole of the right hypochondrium, the greater part of the epigastrium, and extending into the left hypochondrium as far as the mammary line. In the male it weighs from fifty to sixty

ounces; in the female, from forty to fifty. It is relatively much larger in the fœtus than in the adult, constituting, in the former, about one-eighteenth, and in the latter, about one-thirty-sixth of the entire body-weight. Its greatest transverse measurement is from eight to nine inches. Vertically, near its lateral or right surface, it measures about six or seven inches, while its greatest antero-posterior diameter is on a level with the upper end of the right kidney and is from four to five inches. Opposite the vertebral column its measurement from before backward is reduced to about three inches. Its consistence is that of a soft solid; it is, however, friable and easily lacerated; its color is a dark reddish-brown, and its specific gravity is 1.05.

To obtain a correct idea of its shape, it must be hardened *in situ*, and it will then be seen to present the appearance of a wedge, the base of which is directed to the right and the thin edge toward the left. Symington describes its shape as that "of a right-angled triangular prism with the right angles rounded off." It possesses five surfaces, viz., a **superior, inferior, anterior, posterior,** and a **right lateral surface.**

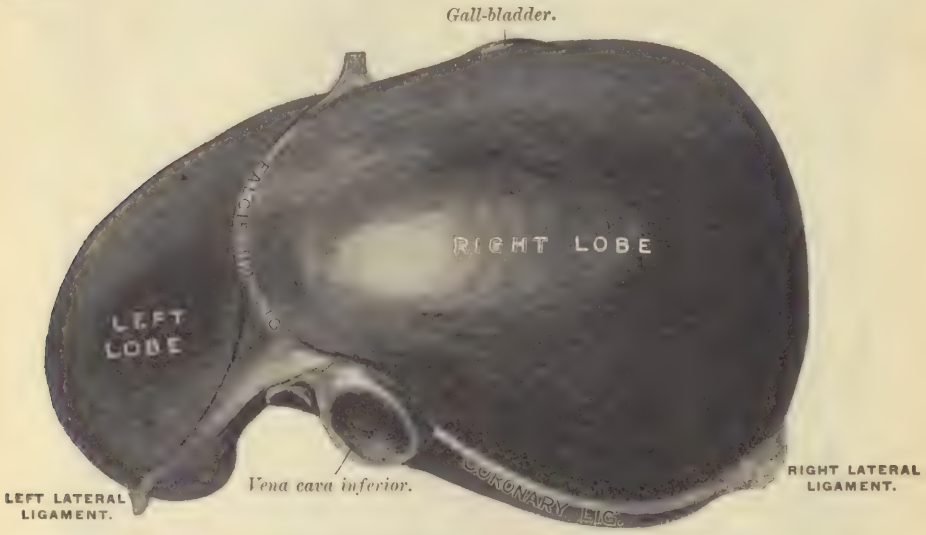

FIG. 936.—The liver. Upper surface. (Drawn from His's models.)

The superior and anterior surfaces are separated from each other by a thick rounded border, and are attached to the Diaphragm and anterior abdominal wall by a triangular or falciform fold of peritoneum, the **suspensory** or **falciform ligament,** which divides the liver into two unequal parts, termed the **right** and **left lobes** (Figs. 936, 940, and 941). Except along the line of attachment of this ligament to the liver, the superior and anterior surfaces are covered by peritoneum.

The Superior Area or Surface (*facies superior*) (Fig. 936).—The superior area or surface comprises a part of both lobes. Spalteholz considers as parts of the superior surface the right surface and the anterior surface. The superior surface is convex, and fits under the vault of the Diaphragm; its central part, however, presents a shallow depression, the **cardiac depression** (*impressio cardiaca*), which corresponds with the position of the heart on the upper surface of the Diaphragm. It is separated from the anterior, posterior, and lateral surfaces by thick, rounded borders. Its left extremity is continued into the under surface by a prominent sharp margin.

The Anterior Area or Surface.—The anterior area or surface is large and triangular in shape, comprising also a part of both lobes. It is directed forward,

and the greater part of it is in contact with the Diaphragm, which separates it from the right lower ribs and their cartilages. In the middle line it lies behind

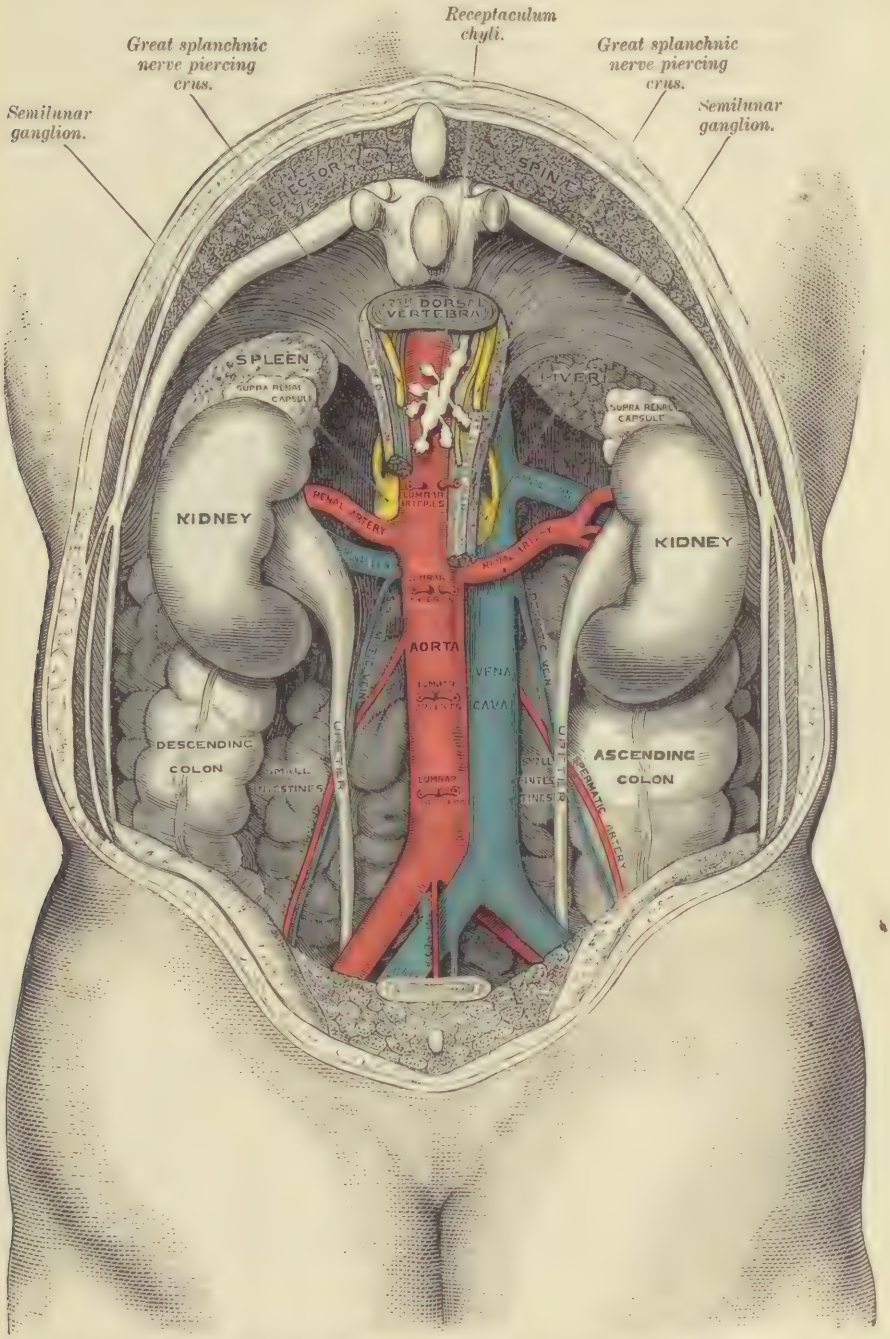

FIG. 937.—The relations of the viscera and large vessels of the abdomen. (Seen from behind, the last dorsal vertebra being well raised.)

the ensiform cartilage, to the left of which it is protected by the seventh and eighth left costal cartilages. In the angle between the diverging rib cartilages of opposite sides the anterior surface is in contact with the abdominal wall. It

is continuous with the inferior surface by a sharp margin, and with the superior and lateral surfaces by thick rounded borders.

The Lateral or Right Area or Surface (Figs. 936 and 938).—The lateral or right area or surface is convex from before backward and slightly so from above downward. It is directed toward the right side, forming the base of the wedge, and lies against the lateral portion of the Diaphragm, which separates it from the lower part of the left pleura and lung, outside which are the right costal arches from the seventh to the eleventh inclusive.

The Under or Visceral Area or Surface (*facies inferior*) (Figs. 938 and 939).—The under or visceral area or surface is uneven, concave, directed downward and backward and to the left, and is in relation with the stomach and duodenum, the hepatic flexure of the colon, and the right kidney. The surface is divided by a longitudinal fissure into a right and a left lobe, and is almost completely invested by peritoneum; the only parts where this covering is absent are where the gall-bladder is attached to the liver and at the transverse fissure, where the two layers of the lesser omentum are separated from each other by the blood-vessels and duct of the viscus. The under surface of the left lobe presents to the right and near the centre a rounded eminence, the **omental tuberosity** (*tuber omentale*) (Fig. 938), which is in contact with the lesser omentum. It is surrounded by a broad depression, the **gastric surface or impression** (*impressio gastrica*), with which the stomach is in contact. Between the gall-bladder and the left lobe is the **quadrate lobe.** The quadrate lobe is bounded to the left by the **umbilical fissure** or the **fissure of the umbilical vein** (*fossa venae umbilicalis*), which is the anterior portion of the longitudinal fissure and lodges the **round ligament** (*ligamentum teres*). The under surface of the right lobe is divided into two unequal portions by a fossa, which lodges the gall-bladder and is called the **fossa vesicalis** (*fossa vesicae felleae*); the portion to the left, the smaller of the two, is somewhat oblong in shape, its antero-posterior diameter being greater than its transverse. It is known as the **quadrate lobe** (*lobus quadratus*), and is in relation with the pyloric end of the stomach (*impressio pylorica*) and the first portion of the duodenum. The portion of the under surface of the right lobe to the right of the fossa vesicalis presents two shallow concave impressions, one situated behind the other, the two being separated by a ridge. The anterior of these two impressions, the **colic impression** (*impressio colica*), is produced by the hepatic flexure of the colon; the posterior, the **renal impression** (*impressio renalis*), is occupied by the upper end of the right kidney (Fig. 938). To the inner side of the latter impression is a third and slightly marked impression, lying between it and the neck of the gall-bladder. This is caused by the second portion of the duodenum, and is known as the **duodenal impression** (*impressio duodenalis*). Just in front of the vena cava is a narrow strip of liver tissue, the **caudate lobe,** which connects the right inferior angle of the Spigelian lobe to the under surface of the right lobe. Immediately below it is the foramen of Winslow.

The Posterior Area or Surface (*facies posterior*) (Figs. 937 and 939).—The posterior area or surface is rounded and broad behind the right lobe, but narrow on the left. Over a large part of its extent it is not covered by peritoneum; this **uncovered area** (Fig. 938) is about three inches broad, and is in direct contact with the Diaphragm, being united to it by areolar tissue. In this tissue are numerous small veins which join the portal circulation to the systemic circulation. The uncovered area is marked off from the upper surface by the line of reflection of the upper or anterior layer of the coronary ligament. It is in the same way marked off from the under surface of the liver by the line of reflection of the lower layer of the **coronary ligament** (Fig. 940). In its centre the posterior surface is deeply notched for the vertebral column and crura of the Diaphragm, and to the right of this it is indented for the inferior vena cava (*fossa venae cavae*), which is often

partly embedded in its substance. Close to the right of this indentation and immediately above the renal impression is a small triangular depressed area, the **suprarenal impression** (*impressio suprarenalis*) (Fig. 938), the greater part of which is devoid of peritoneum; it lodges the right suprarenal capsule, which is inserted between the liver and Diaphragm. To the left of the fossa for the inferior vena cava is the **Spigelian lobe,** which lies between the **fissure for the vena cava** and the fissure for the **ductus venosus.** Below and in front it projects and forms part of the posterior boundary of the transverse fissure. Here, to the right, it is connected with the under surface of the right lobe of the liver by the caudate lobe, and to the left it presents a tubercle, the **tuberculum papillare** (Fig. 938). It is opposite the tenth and eleventh dorsal vertebrae, and rests upon the aorta and crura of the Diaphragm, being covered by the peritoneum of the lesser sac. The lobe is nearly vertical in position, and is directed backward; it is longer from above downward than from side to side, and is somewhat concave in the transverse direction. On the posterior surface to the left of the Spigelian lobe is a groove, the **oesophageal groove** (*impressio oesophagea*), indicating the position of the abdominal portion of the oesophagus (Fig. 938).

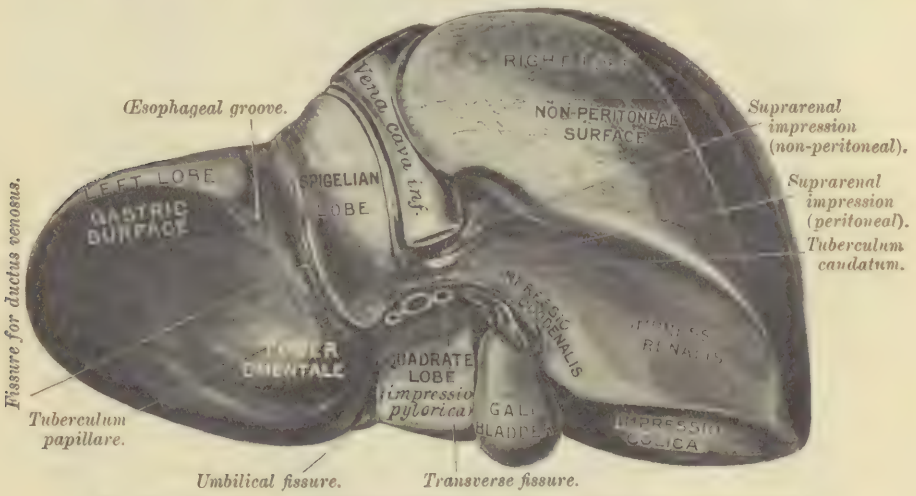

FIG. 938.—The liver. Posterior and inferior surfaces. (Drawn from His's models.)

Prof. Cunningham divides the liver into two surfaces, a **visceral** and a **parietal,** and subdivides the parietal surface into a **posterior area** and **superior area,** an **anterior area** and a **right area.** The parietal surface is separated from the visceral surface by the inferior border or margin.

The **inferior border** or **margin** (*margo inferioris*), posteriorly, is rather ill defined. It is the lower margin of the posterior surface; it follows the line of rib and is in contact with the right kidney. At the right side the lower margin is thick and distinct, and, as a rule, projects slightly below the thorax. The front of the inferior margin is called the **anterior margin** (*margo anterior*). It is a sharp edge which, on inspiration, corresponds to an oblique line on the abdominal wall drawn from "a point half an inch below the margin of the ribs (tip of tenth costal cartilage), on the right side, to a point an inch below the nipple on the left, and extending down in the middle line to a point half-way between the gladiolus and the umbilicus."[1]

In men the anterior margin of the liver often corresponds to the lower margin of the ribs, but in women and children it is usually below the ribs in the line

[1] Ambrose Birmingham, in Cunningham's Text-book of Anatomy.

indicated above. Opposite the attachment of the falciform ligament the anterior border often exhibits a deep notch, the **umbilical notch** (*incisura umbilicalis*), which is the anterior end of the fossa venae umbilicalis. Another notch, sometimes present, corresponds to the fundus of the gall-bladder, and is known as the **notch of the gall-bladder** (*incisura vesicae felleae*).

The **left extremity of the inferior margin of the liver** is thin and flattened from above downward. The margin passes posteriorly around the free end of the left lobe and terminates posteriorly at the oesophageal groove.

Fissures.—Five fissures are seen upon the under and posterior surfaces of the liver, which serve to divide it into five lobes. They are: the **umbilical fissure**, the **fissure of the ductus venosus**, the **transverse fissure**, the **fissure for the gall-bladder**, and the **fissure for the inferior vena cava**. They are arranged in the form of the letter H. The left limb of the H is known as the **longitudinal fissure**. The right limb is formed in front by the **fissure for the gall-bladder**, and behind by the **fissure for the inferior vena cava**; these two fissures are separated from each other by the caudate lobe. The connecting bar of the H is the **transverse** or **portal fissure**. It separates the quadrate lobe in front from the caudate and Spigelian lobes behind.

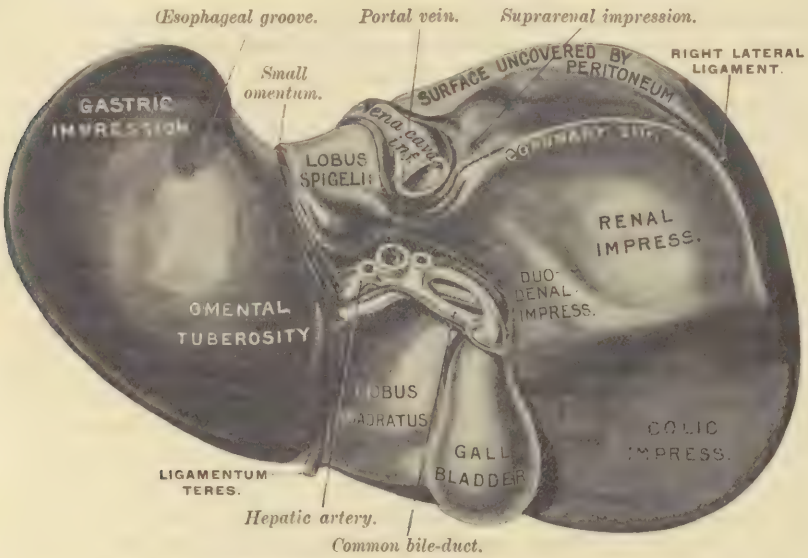

FIG. 939.—Posterior and under surfaces of the liver. (From Ellis.)

The Longitudinal Fossa or Fissure (*fossa longitudinalis sinistra*).—The longitudinal fissure is a deep groove, which extends from the notch on the anterior margin of the liver to the upper border of the posterior surface of the organ. It separates the right and left lobes; the **Transverse Fissure** (Fig. 938) joins it, at right angles, and divides it into two parts. The anterior part is called the **umbilical fossa** or **fissure** (*fossa venae umbilicalis*) (Fig. 938); it is deeper than the posterior, and lodges the umbilical vein in the fœtus, and its remains (the round ligament) in the adult; the posterior part contains the ductus venosus, and is known as the **fissure of the ductus venosus**. This fissure lies between the quadrate lobe and the left lobe of the liver, and is often partially bridged over by a prolongation of the hepatic substance, the **pons hepatis**.

The **Fissure** or **Fossa of the Ductus Venosus** (*fossa ductus venosi*) (Fig. 938) is the back part of the longitudinal fissure, and is situated mainly on the posterior surface of the liver. It lies between the left lobe and the lobe of Spigelius. It

lodges in the fœtus the ductus venosus, and in the adult a slender fibrous cord, the obliterated remains of that vessel.

The Transverse or Portal Fissure (*porta hepatis*) (Fig. 938).—The transverse or portal fissure is a short but deep fissure, about two inches in length, extending transversely across the under surface of the left portion of the right lobe, nearer to its posterior surface than its anterior border. It joins, nearly at right angles, with the longitudinal fissure, and separates the quadrate lobe in front from the caudate and Spigelian lobes behind. By the older anatomists this fissure was considered the gateway (*porta*) of the liver; hence the large vein which enters at this fissure was called the **portal vein** (Fig. 939). Besides this vein, the fissure transmits the hepatic artery and nerves, and the hepatic duct and lymphatics. At their entrance into the fissure, the hepatic duct lies in front and to the right, the hepatic artery to the left, and the portal vein behind and between the duct and artery.

The Fossa or Fissure for the Gall-bladder (*fossa vesicae felleae*).—The fossa or fissure for the gall-bladder is a shallow, oblong fossa, placed on the under surface of the right lobe, parallel with the longitudinal fissure. It extends from the anterior free margin of the liver, which is notched for its reception, to the right extremity of the transverse fissure.

The Fissure or Fossa for the Inferior Vena Cava (*fossa venae cavae*) (Fig. 938).—The fissure or fossa for the inferior vena cava is a short, deep fissure, in some cases a complete canal, in consequence of the substance of the liver occasionally surrounding the vena cava. It extends obliquely upward from the lobus caudatus, which separates it from the transverse fissure, on the posterior surface of the liver, and separates the Spigelian from the right lobe. On slitting open the inferior vena cava the orifices of the hepatic veins will be seen opening into this vessel at its upper part, after perforating the floor of this fissure.

Lobes.—The lobes of the liver, like the ligaments and fissures, are five in number—the **right lobe**, the **left lobe**, the **lobus quadratus**, the **lobus Spigelii**, and the **lobus caudatus**, the last three being merely parts of the right lobe.

The Right Lobe (*lobus hepatis dexter*) (Figs. 936 and 938).—The right lobe is much larger than the left; the proportion between them being as six to one. It occupies the right hypochondrium, and is separated from the left lobe, on its upper and anterior surfaces by the falciform ligament; on its under and posterior surfaces by the longitudinal fissure; and in front by the umbilical notch. It is of a somewhat quadrilateral form, its under and posterior surfaces being marked by three fissures—the transverse fissure, the fissure for the gall-bladder, and the fissure for the inferior vena cava, which separate its left part into three smaller lobes—the lobus Spigelii, lobus quadratus, and lobus caudatus. On it are seen four shallow impressions: one in front, for the hepatic flexure of the colon; a second behind, for the right kidney; a third internal, between the last-named and the gall-bladder, for the second part of the duodenum; and a fourth on its posterior surface, for the suprarenal capsule.

The **Lobus Quadratus** or **Square Lobe** (Figs. 938 and 939) is situated on the under surface of the right lobe, is bounded in front by the inferior margin of the liver; behind, by the transverse fissure; on the right, by the fissure of the gall-bladder; on the left, by the umbilical fissure.

The **Lobus Spigelii** (*lobus caudatus* [*Spigeli*]) (Figs. 938 and 939) is situated upon the posterior surface of the right lobe of the liver. It looks directly backward, and is nearly vertical in direction. It is bounded, above, by the upper layer of the coronary ligament; below, by the transverse fissure; on the right, by the fissure for the vena cava; and on the left, by the fissure for the ductus venosus. Its left upper angle forms part of the groove for the œsophagus. What is here called the lobus Spigelii, Spalteholz calls the lobus caudatus of Spigelius.

The **Lobus Caudatus** or **Tuberculum Caudatum** (*processus caudatus*) (Fig. 938), or tailed lobe, is a small elevation of the hepatic substance extending obliquely outward, from the lower extremity of the Spigelian lobe to the under surface of the right lobe. It is situated behind the transverse fissure, and separates the fissure for the gall-bladder from the commencement of the fissure for the inferior vena cava. What is here called the lobus caudatus, Spalteholz calls the processus caudatus of the lobus caudatus of Spigelius.

The Left Lobe (*lobus hepatis sinister*) (Figs. 936 and 938).—The left lobe is smaller and more flattened than the right. It is situated in the epigastric and left hypochondriac regions. Its upper surface is slightly convex; its under surface is concave, and presents a shallow depression for the stomach, the **gastric impression**. This is situated in front of the groove for the oesophagus, and is separated from the longitudinal fissure by the **omental tuberosity,** which lies against the small omentum and lesser curvature of the stomach. The posterior end of the left lobe frequently exhibits a flat projection, composed of connective tissue, and called the **appendix fibrosa hepatis.** In the adult, portions only of bile-ducts are present in it. In the newborn it is a definite portion of secreting liver substance, which later undergoes connective-tissue transformation.

Ligaments.—The liver is connected to the under surface of the Diaphragm and the anterior walls of the abdomen and the inferior vena cava by six ligaments, four of which are peritoneal folds; the other two, which are the round ligament and the ligament of the ductus venosus, are fibrous cords, resulting from the obliteration of fœtal vessels. These ligaments are the **falciform**, two **lateral, coronary, round,** and the **ligament of the ductus venosus**. It is also attached to the lesser curvature of the stomach by the gastro-hepatic or small omentum.

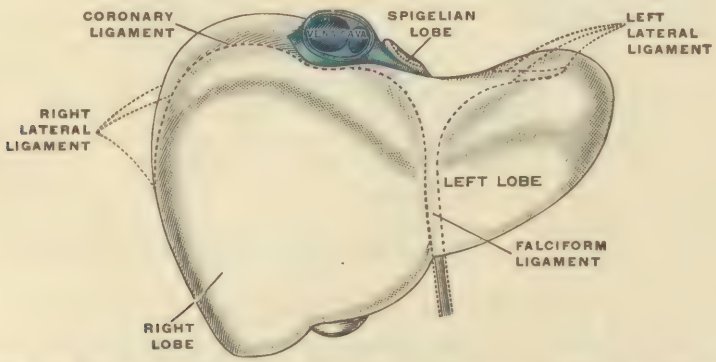

FIG. 940.—The peritoneal ligaments of the liver. (Schematic.) (Poirier and Charpy.)

The Falciform, Broad or Suspensory Ligament (*ligamentum falciforme hepatis*) (Figs. 936, 940, and 941).—The falciform or suspensory ligament is a broad and thin antero-posterior peritoneal fold, falciform in shape, its base being directed downward and backward, its apex upward and backward. It is attached by one margin to the under surface of the Diaphram, and the posterior surface of the sheath of the right Rectus muscle to within one inch of the umbilicus; by its hepatic margin it extends from the notch on the anterior margin of the liver, as far back as its posterior surface.

The free edge or base of the falciform ligament reaches from a little above and to the right of the umbilicus to the umbilical fissure on the anterior margin of the liver. This free edge contains between its folds the round ligament of the liver. On the posterior surface of the liver the two peritoneal folds which constitute the falciform ligament separate, the right fold passing into the upper fold of the coronary ligament, the left fold passing into the upper fold of the left lateral ligament.

The Lateral Ligaments (Figs. 936 and 940).—The lateral ligaments are two in number, and are called the **right** and **left lateral ligaments.**

The **Right Lateral Ligament** (*ligamentum triangulare dextrum*) (Figs. 936 and 940) is in reality the right extremity of the coronary ligament. This ligament is triangular in form, runs from the liver to the Diaphragm, and is formed by the apposition of the upper and lower layers of the coronary ligament. It is attached to the liver between its lateral and inferior surfaces.

The **Left Lateral Ligament** (*ligamentum triangulare sinistrum*) (Figs. 936 and 940) is also formed by apposition of the upper and lower layers of the coronary ligament. It is triangular in form, runs from the liver to the Diaphragm, and is longer than the right lateral ligament. It is attached to the upper surface of the left lobe, where it lies, in front of the oesophageal opening in the Diaphragm.

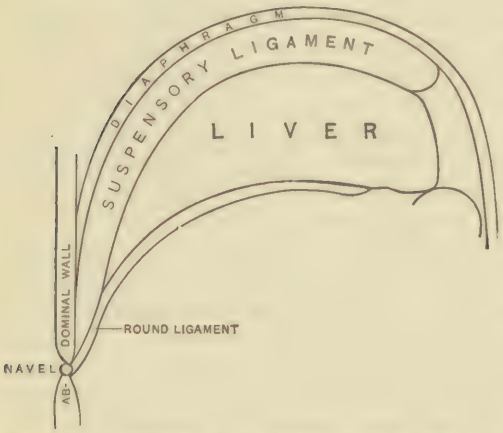

FIG. 941.—Diagram to show the relations of the falciform or suspensory and round ligaments to the liver and the abdominal wall. (Gerrish.)

The Coronary Ligament (*ligamentum coronarium hepatis*) (Figs. 936 and 940).—The coronary ligament connects the posterior surface of the liver to the Diaphragm. It is formed by the reflection of the peritoneum from the Diaphragm on to the upper and lower margins of the posterior surface of the liver. The coronary ligament consists of two layers, which are continuous on each side with the lateral ligaments, and, in front, with the falciform ligament. Between the layers a large triangular area is left uncovered by peritoneum, and is connected to the Diaphragm by firm areolar tissue.

The Round Ligament (*ligamentum teres hepatis*) (Figs. 939 and 941).—The round ligament is a fibrous cord resulting from the obliteration of the fœtal umbilical vein. It ascends from the umbilicus, in the free margin of the falciform ligament, to the notch in the anterior border of the liver, from which it may be traced along the umbilical fissure on the under surface of the liver, to the left branch of the portal vein.

The **Ligament of the Ductus Venosus** (*ligamentum venosum* [*Arantii*]) is composed of slender bundles of fibrous tissue, and results from the obliteration of the ductus venosus of the fœtus. It arises from the left branch of the portal vein, almost opposite the insertion of the round ligament, passes backward in the fissure of the ductus venosus, and, as it emerges from the liver, is attached to the vena cava.

Support and Movability of the Liver.—The liver is movable within certain narrow limits. It moves with respiration. On inspiration it moves down with the Diaphragm to distinctly below the costal arch in the right nipple line. Much discussion has taken place as to what supports the liver in place. Symington asserted that the ligaments do not give support, because they lie relaxed. Other observers (Graham, Steele) apparently demonstrate that the peritoneal ligaments do give some support to the liver. The connective tissue which unites the uncovered area of the right lobe of the liver to the Diaphragm and the hepatic veins which join the vena cava (Faure) do give distinct support. The chief factor in the support of the liver is the intra-abdominal pressure resulting from the tonic contraction of the abdominal muscles. When abdominal tension is normal the intestines are driven up and become a bed for the liver. Intrahepatic vascular tension aids in supporting the liver (Glénard).

Abnormalities of the Liver.—The liver may be divided into many lobules, and such lobulation is most evident on the parietal surface of the right lobe. Lobulation is probably a pathological change. Occasionally the right lobe is small and the left large.

The editor, in performing an abdominal operation, encountered a liver the left lobe of which was so large and the right so small as to suggest transposition or rotation of the organ. Such a change may result from abnormality of the fœtal circulation or from syphilitic disease of the right lobe, producing cicatricial contraction.[1] The left lobe may be very small; sometimes it is rudimentary. When the left lobe is very small an unusual amount of stomach is visible, and the entire gall-bladder can be seen from the front. In such a case the gall-bladder is usually displaced and it may actually "lie with its long axis in the transverse axis of the body."[2]

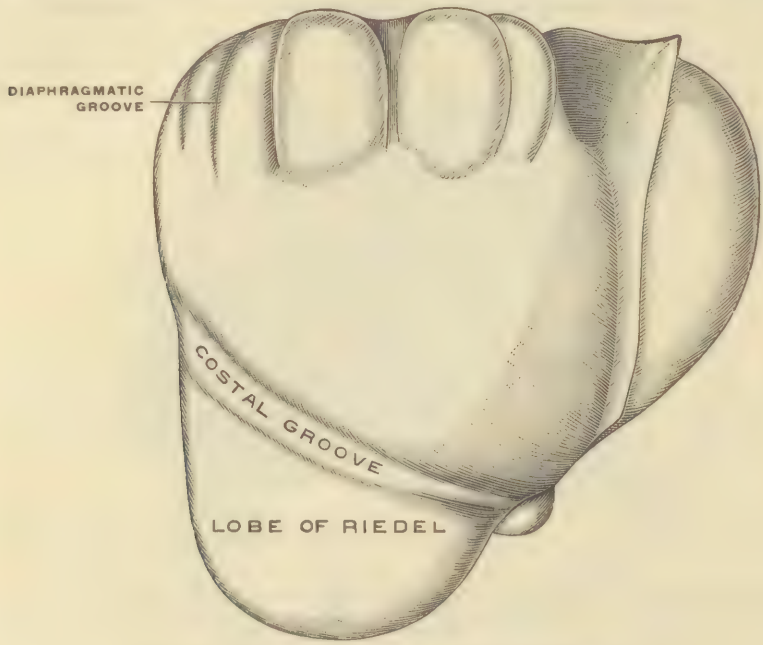

FIG. 942.—Deformed female liver. (Poirier and Charpy.)

Atrophy of the left lobe is usually a congenital defect, but may result from syphilis. Small accessory lobes, about one inch in length, are not uncommon, and they are most often met with on the visceral surface of the right lobe. "When markedly pedunculated, they may form accessory livers. The Spigelian lobe is sometimes curiously pedunculated."[3]

Accessory livers are fragments of hepatic tissue or rests, which are entirely separated from the liver. They are seldom met with. When they do exist their most common situation is in the suspensory ligament, but they have been found in the great omentum, in the peritoneum, wall of the gall-bladder, and in other situations. They may be congenital or may be due to atrophy of the pedicle of an accessory lobe or of a pedunculated lobe. **Tight lacing** alters the shape and position of the liver (Fig. 942). It may flatten the dome and increase the length of the anterior surface, this change being especially obvious in the right lobe, and a costal groove may be formed by the pressure of a rib. "When the elongated right lobe passes over the right kidney, there is atrophy of the hepatic substance

[1] H. D. Rolleston on Diseases of the Liver. [2] Ibid. [3] Ibid.

and thickening of the capsule, which is opaque and forms a hinge-like ligament between the main part of the right lobe above and the constricted lower portion. This lobe is variously termed **partial hepatoptosis, constriction lobe,** or the **sustentacular formation of the right lobe** (Hertz). The constriction furrow is produced by the pressure of the corset in front and the resistance of the kidney behind. The constriction lobe tapers to a point, so that the shape of the liver, as seen from the front, is that of a right-angled triangle, with the apex downward."[1] The condition resembles **Riedel's lobe.** The left lobe may also project down, but not so markedly. Tight lacing may cause the entire organ to occupy a level higher than normal. Such a liver is thick and excessively convex above and thin below, and reaches to or laps over the spleen. In severe cases the superior surface is thrown into antero-posterior creases or folds. **Linguiform** or **tongue-like lobe, Riedel's lobe** or **floating lobe** (Fig. 942), may be congenital, may be due to tight lacing, or may arise in cholelithiasis or cholecystitis from the traction of adhesions. Such a lobe comes off from the right lobe. It may be a tapering mass of liver tissue, it may have a thin pedicle of liver tissue, or its pedicle may be merely a double fold of peritoneum. The gall-bladder may lie upon its under surface, or may be placed to the left of it.

Vessels.—The blood-vessels connected with the liver are the **hepatic artery,** the **portal vein** and the **hepatic veins.**

Fig. 943.—Schematic section of the liver. The fibron tunic shown in black and tne capsule of Glisson in red.

The **Hepatic Artery** and **Portal Vein** (Figs. 418, 419, 489, and 944), accompanied by numerous lymphatics and nerves, ascend to the transverse fissure between the layers of the gastro-hepatic omentum, and in front of the foramen of Winslow. The **hepatic duct,** lying in company with them, descends from the transverse fissure between the layers of the same omentum. The relative position of the three structures in the lesser omentum (Fig. 859) is as follows: the hepatic duct lies to the right, the hepatic artery to the left, and the portal vein behind and between the other two. They enter the transverse fissure in the above-described order, but in that fissure undergo rearrangement, the duct being in front, the artery in the middle, and the vein behind. The artery, the vein, and the duct divide into a right and left branch and several smaller branches, and within the organ the vessels from the three sources accompany each other and divide at the same points; so each branch of the portal vein is accompanied by a branch of the hepatic artery and of the duct. They are enveloped in a loose areolar tissue, the **capsule of Glisson** (Fig. 943), which accompanies the vessels in their course through the *portal canals* in the interior of the organ.

The Hepatic Veins (Fig. 421).—The hepatic veins convey the blood from the liver. They commence in the substance of the liver, in the capillary terminations of the portal vein and hepatic artery; these tributaries, gradually uniting, usually form three

[1] Rolleston, on Diseases of the Liver.

veins, which converge toward the posterior surface of the liver and open into the portion of the inferior vena cava situated in the groove at the back part of this organ. Of these three veins, one from the right and another from the left lobe open obliquely into the vena cava; that from the middle of the organ and lobus Spigelii having a straight course.

The hepatic veins have very little cellular investment; what there is binds their parietes closely to the walls of the canals through which they run; so that, on section of the organ, these veins remain widely open and solitary (Fig. 946), and may be easily distinguished from the branches of the portal vein (Fig. 947), which are more or less collapsed, and always accompanied by an artery and duct. The hepatic veins are destitute of valves.

Structure.—The substance of the liver is composed of **lobules** held together by extremely fine areolar tissue, and of the ramifications of the portal vein, hepatic duct, hepatic artery, hepatic veins, lymphatics, and nerves, the whole being invested by a serous and a fibrous coat.

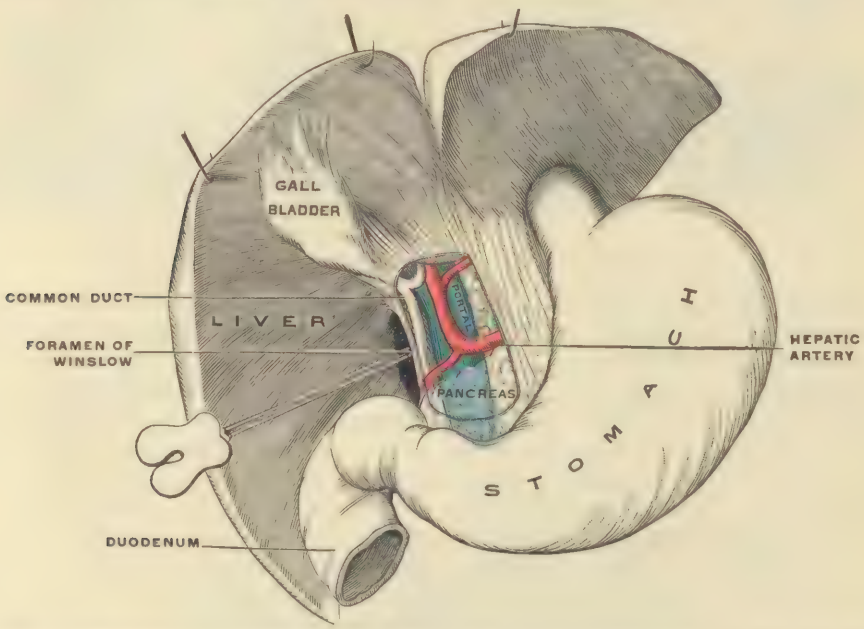

FIG. 944.—The relations of the vessels as they pass into the transverse fissure of the liver. (Poirier and Charpy.)

The Serous Coat (*tunica serosa*).—The serous coat is derived from the peritoneum, and invests the greater part of the surface of the organ. It is intimately adherent to the fibrous coat.

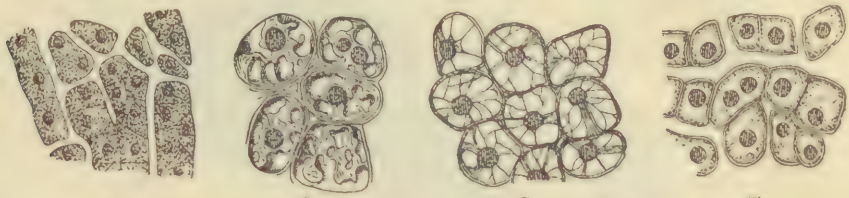
The Areolar or Fibrous Coat (*capsula fibrosa* [*Glissoni*]).—The areolar or fibrous coat lies beneath the serous investment and covers the entire surface of the organ. It is difficult of demonstration, excepting where the serous coat is deficient. At the transverse fissure it is thick and evident, is known as the **capsule of Glisson,** and envelops the vessels which enter the liver and passes with them along the portal canals. The areolar tissue which surrounds and binds together the liver lobules is continuous with the areolar coat.

The Lobules (*lobuli hepatis*) (Fig. 949).—The lobules form the chief mass of the hepatic substance; they may be seen either on the surface of the organ or by making a section through the gland. They are small granular bodies about the size of a millet-seed, measuring from one-twentieth to one-tenth of an inch in diameter. In the human subject their outline is very irregular, but in some of the lower

animals (for example, the pig) they are well defined, and when divided transversely have a polygonal outline. If divided longitudinally they are more or less foliated or oblong. The bases of the lobules are clustered around the smallest radicles of the hepatic veins (*sublobular veins*), to which each is connected by means of a small branch which issues from the centre of the lobule (*intralobular vein*). The remaining part of the surface of each lobule is imperfectly isolated from the surrounding lobules by a thin stratum of areolar tissue in which are **ducts** and a plexus of vessels, the **interlobular plexus** (Figs. 948 and 949). In some animals, as the pig, the lobules are completely isolated one from another by this interlobular areolar tissue.

If one of the sublobular veins be laid open, the bases of the lobules may be seen through the thin wall of the vein on which they rest, arranged in the form of a tessellated pavement, the centre of each polygonal space presenting a minute aperture, the mouth of an intralobular vein (Fig. 946).

Microscopic Appearance. – Each lobule is composed of a mass of cells, **hepatic cells** (Fig. 945), surrounded by a dense capillary plexus, composed of vessels which



A *B* *C* *C′*

Fig. 945.—The hepatic cells at different stages of digestion. (Heidenhain.)

penetrate from the circumference to the centre of the lobule, and terminate in a single straight central vein, which runs through its centre, to open at its base into one of the radicles of the hepatic vein. Between the cells are also the minute commencements of the bile-ducts. Therefore in the lobule we have all the essentials of a secreting gland; that is to say: (1) **cells**, by which the secretion is formed; (2) **blood-vessels**, in close relation with the cells, containing the blood from which the secretion is derived; and (3) **ducts**, by which the secretion, when formed, is carried away. Each of these structures will have to be further considered.

(1) The **Hepatic Cells** are epithelial in nature and of more or less spheroidal form, but may be rounded, flattened, or many-sided from mutual compression. They vary in size from the $\frac{1}{1000}$ to the $\frac{1}{2000}$ of an inch in diameter. They consist of a honeycomb network (Klein) without any cell-wall, and contain one or sometimes two distinct nuclei. In the nucleus is a highly refracting nucleolus with granules. Embedded in the honeycomb network are numerous yellow particles, the coloring matter of the bile, and oil-globules. The cells adhere together by their surfaces so as to form rows, which radiate from the centre to the circumference of the lobules.[1] As stated above, they are the chief agents in the secretion of the bile.

(2) **The Blood-vessels.**—The blood in the capillary plexus around the liver-cells is brought to the liver principally by the portal vein, but also to a certain extent by the hepatic artery. For the sake of clearness the distribution of the blood derived from the hepatic artery may be considered first.

The **Hepatic Artery**, entering the liver at the transverse fissure with the portal vein and hepatic duct, ramifies with these vessels through the portal canals. It gives off **vaginal branches** which ramify in the capsule of Glisson, and appear to be destined chiefly for the nutrition of the coats of the large vessels, the ducts,

[1] Delépine states that there are evidences of the arrangement of these cells in the form of columns, which form tubes with narrow lumina branching from terminal bile-ducts. This branching is evidenced by a divergence of the columns from lines extending between adjacent portal vessels. The columns of cells group around terminal bile-ducts, and not around the so-called intralobular veins. (Lancet, 1895, vol. i. p. 1254.) Ed. of 15th English edition.

and the investing membranes of the liver. It also gives off **capsular branches** which reach the surface of the organ, terminating in the fibrous coat in stellate plexuses. Finally it gives off **interlobular branches** (*rami arteriosi interlobulares*) which form a plexus on the outer side of each lobule, to supply its wall and the accompanying bile-ducts. From this plexus lobular branches enter the lobule

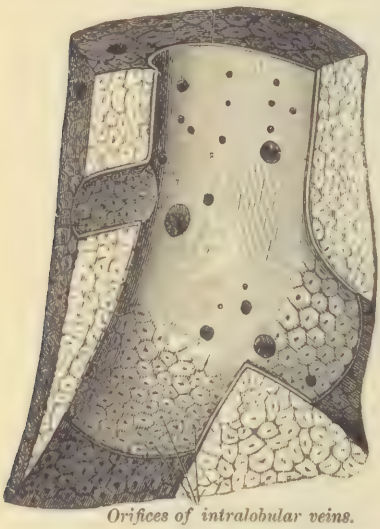


FIG. 946.—Longitudinal section of an hepatic vein. (After Kiernan.)

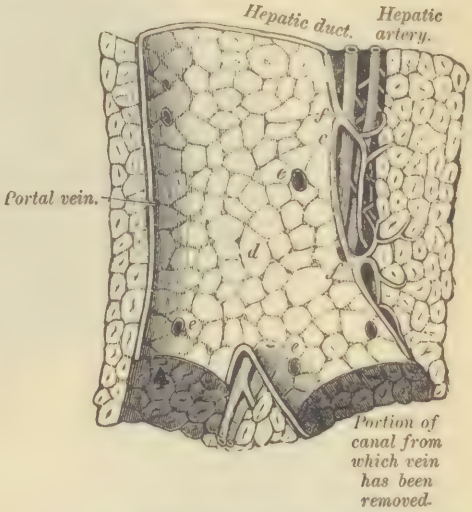

FIG. 947.—Longitudinal section of a small portal vein and canal. (After Kiernan.)

and end in the capillary network between the cells. Some anatomists, however, doubt whether it transmits any blood directly to the capillary network.

The **Portal Vein** also enters at the transverse fissure and runs through the portal canals, enclosed in Glisson's capsule, dividing into branches in its course,

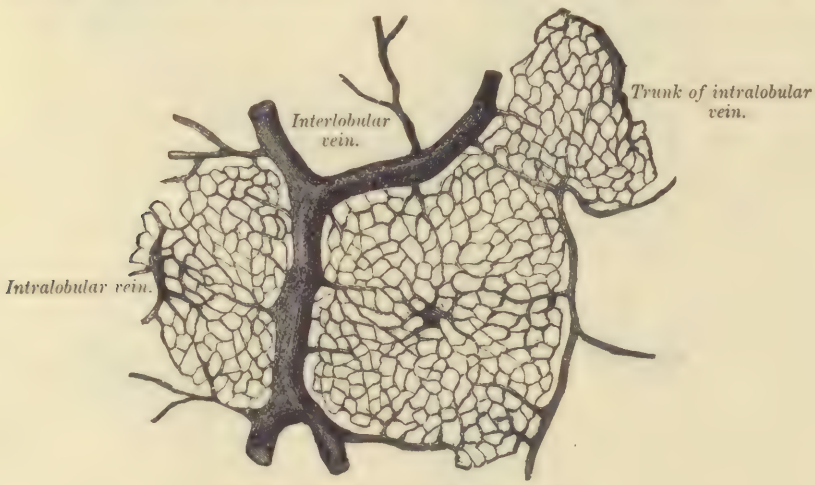

FIG. 948.—Horizontal section of liver (dog.)

which finally break up into a plexus, the **interlobular plexus**, in the interlobular spaces. In their course these branches receive the vaginal and capsular veins, corresponding to the vaginal and capsular branches of the hepatic artery (Fig. 947). Thus it will be seen that all the blood carried to the liver by the portal vein and hepatic artery, except perhaps that derived from the interlobular branches of

the hepatic artery, directly or indirectly finds its way into the interlobular plexus. From this plexus the blood is carried into the lobule by fine branches which pierce its wall and then converge from the circumference to the centre of the lobule, form-

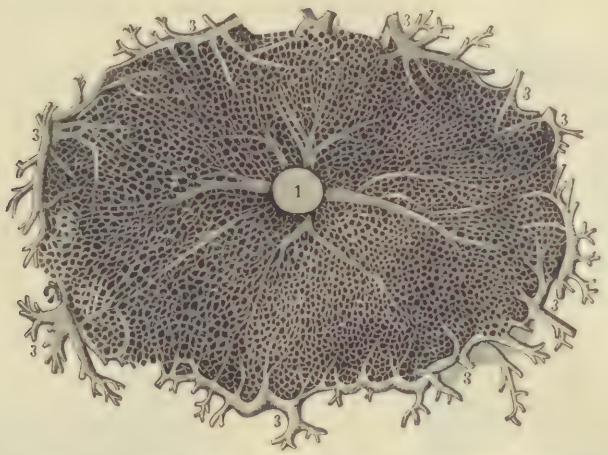

FIG. 949.—Horizontal section of a liver lobule. 1, central vein; 2, converging vessels; 3, interlobular plexus. (Poirier and Charpy.)

ing a number of converging vessels which are connected by transverse branches (Figs. 948 and 949). In the interstices of the network of vessels thus formed are situated, as before said, the liver-cells: and here it is that the blood is brought into

FIG. 950.—*X*-ray picture of the bile-ducts and the pancreatic ducts. (Byron Robinson.)

intimate connection with the liver-cells and the bile is secreted. Arrived at the centre of a lobule, all these minute vessels empty themselves into one vein, of considerable size, which runs down the centre of the lobule from apex to base and is called the **intralobular** or **central vein** (*vena interlobularis*) (Fig. 949). At the

base of the lobule this vein opens directly into the **sublobular vein,** with which the lobule is connected, and which, as before mentioned, is a radicle of the hepatic vein. The sublobular veins, uniting into larger and larger trunks, end at last in the hepatic veins, which do not receive any intralobular veins. Finally, the hepatic veins, as mentioned on page 767, converge to form three large trunks which open into the inferior vena cava, while that vessel is situated in the fissure appropriated to it at the back of the liver.

(3) **The Ducts.**—Having shown how the blood is brought into intimate relation with the hepatic cells in order that the bile may be secreted, it remains now only to consider the way in which the secretion, having been formed, is carried away. Several views have prevailed as to the mode of origin of the hepatic ducts; it seems, however, to be clear that they commence by little passages which are formed between the cells, and which have been termed **intercellular biliary passages, bile-capillaries** or **bile-canaliculi** (*ductus biliferi*). These passages are merely little channels or spaces left between the contiguous surfaces of two cells or in the

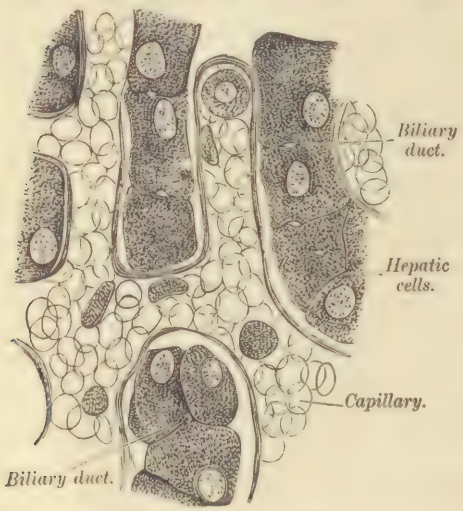

Fig. 951.—Section of liver.

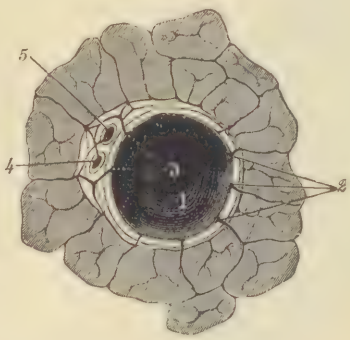

Fig. 952.—A transverse section of a small portal canal and its vessels. 1, portal vein; 2, interlobular branches; 3, vaginal branches; 4, hepatic duct; 5, hepatic artery. (After Kiernan.)

angle where three or more liver-cells meet (Fig. 951), and it seems doubtful whether there is any delicate membrane forming the wall of the channel. Heidenhain, however, thinks they have coats. The channels thus formed radiate to the circumference of the lobule, and, piercing its wall, form a plexus (*interlobular*) between the lobules. From this plexus **interlobular ducts** (*ductus interlobulares*) are derived which pass into the portal canals, become enclosed in Glisson's capsule, and, accompanying the portal vein and hepatic artery (Fig. 952), join with other ducts to form two main trunks, the right and left branches of the hepatic duct, which leave the liver at the transverse fissure, and by their union form the hepatic duct.

Structure.—The coats of the smallest biliary ducts, which lie in the interlobular spaces, are a connective-tissue coat, in which are muscle-cells, arranged both circularly and longitudinally, and an epithelial layer, consisting of short columnar cells. In the larger ducts, which lie in the portal canals, there are a number of orifices disposed in two longitudinal rows, which were formerly regarded as the openings of mucous glands, but which are merely the orifices of tubular recesses. They occasionally anastomose, and from the sides of them saccular dilatations are given off.

Lymphatics of the Liver (Fig. 506).—The lymphatics in the substance of the liver commence in lymphatic spaces around the capillaries of the lobules; they accompany

the vessels of the interlobular plexus, often enclosing and surrounding them. These unite and form larger vessels, which run in the portal canals, enclosed in Glisson's capsule, and emerge at the portal fissure to be distributed in the manner described. Other superficial lymphatics arise from the superficial lobules, pass under the peritoneum, and form a close plexus, where this membrane covers the liver. The first-named group of lymphatics give origin to the deep collecting trunks, the second to the superficial collecting trunks. According to Poirier, Cunéo and Delamare,[1] one group of deep collecting trunks accompanies the portal vein, there being fifteen to eighteen of them emerging from the transverse fissure. They empty into the glands of the hilum. Another group accompanies the hepatic veins. There are five or six trunks which pass through the Diaphragm and terminate in the glands about the vena cava (*intrathoracic glands*). According to the above-cited authorities, the superficial trunks of the superior surface are divided into posterior, anterior, and superior trunks. Some of the posterior trunks terminate in the glands about the coeliac axis, others in the glands about the lower portion of the vena cava in the thorax; others in the glands about the abdominal portion of the oesophagus. The anterior trunks which are limited to the right lobe pass to the glands of the hilum. The superior trunks ascend in the suspensory ligament. Some pass to the glands about the vena cava, just above the Diaphragm; others to the hepatic glands. The balance unite to form a very large trunk, which passes through the Diaphragm and divides into branches which enter the glands back of the base of the ensiform cartilage.

Nerves of the Liver.—The nerves of the liver are derived from the **left pneumogastric** and the **solar plexus of the sympathetic.** The branches of the pneumogastric ascend from in front of the stomach within the lesser omentum. The sympathetic nerves pass along the hepatic artery from the coeliac plexus. The nerves enter the liver at the transverse fissure and accompany the vessels and ducts to the interlobular spaces. Here, according to Korolkow, the medullated fibres are distributed almost exclusively to the coats of the blood-vessels; while the non-medullated fibres enter the lobules and ramify between the cells.

The Excretory Apparatus of the Liver.

The excretory apparatus of the liver consists of (1) the **hepatic duct,** which, as we have seen, is formed by the junction of the two main ducts, which pass out of the liver at the transverse fissure, and are formed by the union of the bile-capillaries; (2) the **gall-bladder,** which serves as a reservoir for the bile; (3) the **cystic duct,** which is the duct of the gall-bladder; and (4) the **common bile-duct,** formed by the junction of the hepatic and cystic ducts.

The Hepatic Duct (*ductus hepaticus*) (Figs. 953, 954, and 956).—Two main trunks of nearly equal size issue from the liver at the transverse fissure, one from the **right,** the other from the **left lobe;** these unite to form the hepatic duct, which then passes downward and to the right for about an inch and a half or two inches, between the layers of the lesser omentum, where it is joined at an acute angle by the cystic duct, and so forms the ductus communis choledochus. The hepatic duct, as it descends from the transverse fissure of the liver, between the two layers of the lesser omentum, lies in company with the hepatic artery and portal vein (Fig. 944).

The Gall-bladder (*vesica fellea*) (Figs. 859, 861, 938, 944, and 953).—The gall-bladder is the reservoir for the bile; it is a conical or pear-shaped musculo-membranous sac, lodged in a fossa on the under surface of the right lobe of the liver, and fixed in it by connective tissue, and extending from near the right extremity of the transverse fissure to the anterior border of the organ. It is

[1] The Lymphatics. Translated and edited by Cecil H. Leaf.

about four inches in length, one inch in breadth at its widest part, and holds from eight to ten drachms. It is divided into a fundus, body, and neck. The **fundus** (*fundus vesicae felleae*), or broad extremity, is directed downward, forward, and to the right, and projects beyond the anterior border of the liver; the **body** (*corpus vesicae felleae*) and **neck** (*collum vesicae felleae*) are directed upward and backward to the left. The neck of the gall-bladder is on a slightly higher level than the lowest point of the gall-bladder; thus the weight of the bile is away from rather than toward the outlet. The upper surface of the gall-bladder is attached to the liver by connective tissue and vessels. The under surface is covered by peritoneum, which is reflected on to it from the surface of the liver. Occasionally the whole of the organ is invested by the serous membrane, and is then connected to the liver by a kind of mesentery.

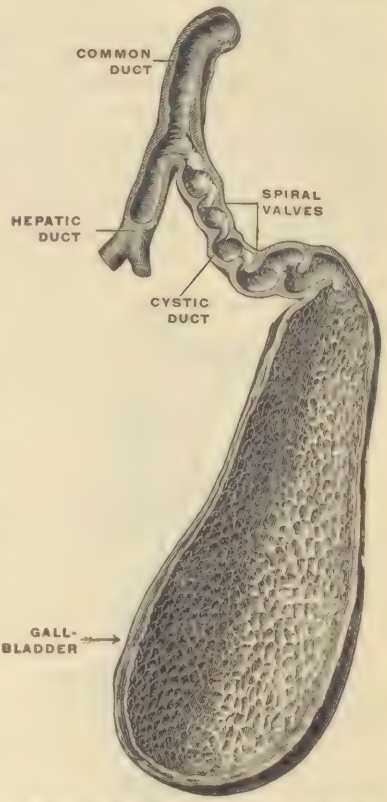

FIG. 953. The gall-bladder and bile-ducts, cut through. (Spalteholz.)

Relations.—The **body of the gall-bladder** is in relation, by its upper surface, with the liver, to which it is connected by areolar tissue and vessels; by its under surface, with the commencement of the transverse colon; and farther back, with the upper end of the descending portion of the duodenum or sometimes with the pyloric end of the stomach or the first portion of the duodenum. The **fundus** is completely invested by peritoneum; it is in relation, in front, with the abdominal parietes, immediately below the ninth costal cartilage; behind, with the transverse arch of the colon. The **neck** is narrow, and curves upon itself like the letter S; at its point of connection with the cystic duct it presents a well-marked constriction.

When the gall-bladder is distended with bile or filled with calculi, the fundus may be felt through the abdominal parietes, especially in an emaciated subject; the relations of this sac will also serve to explain the occasional occurrence of abdominal biliary fistulae, through which biliary calculi may pass out, and of the passage of calculi from the gall-bladder into the stomach, duodenum, or colon, which occasionally happens.

Structure.—The gall-bladder consists of three coats—**serous, fibrous** and **muscular,** and **mucous.**

The **External** or **Serous Coat** (*tunica serosa vesicae felleae*) is derived from the peritoneum; it completely invests the fundus, but covers the body and neck only on their under surfaces.

The **Fibro-muscular Coat** (*tunica muscularis vesicae felleae*) is a thin but strong layer which forms the framework of the sac, consisting of dense fibrous tissue which interlaces in all directions and is mixed with plain muscular fibres which are disposed chiefly in a longitudinal direction, a few running transversely.

The **Internal** or **Mucous Coat** (*tunica mucosa vesicae felleae*) is loosely connected with the fibrous layer. It is generally tinged with a yellowish-brown color, and is everywhere elevated into minute **rugae,** by the union of which numerous meshes are formed, the depressed intervening spaces having a polygonal outline. The meshes are smaller at the fundus and neck, being most developed about the centre

of the sac. Opposite the neck of the gall-bladder the mucous membrane projects inward in the form of oblique ridges or folds, forming a sort of screw-like or *spiral* valve (Fig. 953).

The mucous membrane is covered with columnar epithelium, and secretes an abundance of thick viscid mucus; it is continuous through the hepatic duct with the mucous membrane lining the ducts of the liver, and through the ductus communis choledochus with the mucous membrane of the duodenum.

The Cystic Duct (*ductus cysticus*).—The cystic duct, the smallest of the three biliary ducts, is about an inch and a half in length. It passes obliquely downward and to the left from the neck of the gall-bladder, and joins the hepatic duct to form the common bile-duct. It lies in the gastro-hepatic omentum in front of the portal

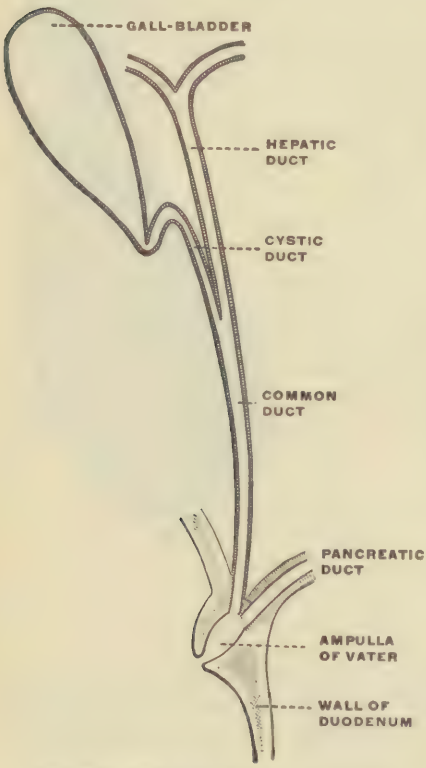

Fig. 954.—The biliary ducts. Schematic. (Poirier and Charpy.)

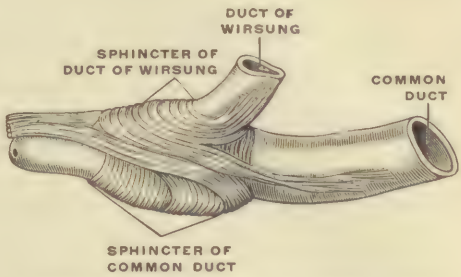

Fig. 955.—The sphincter of the common bile-duct. (Poirier and Charpy.)

vein, the hepatic artery lying to its left side. The mucous membrane lining its interior is thrown into a series of crescentic folds, from five to twelve in number, similar to those found in the neck of the gall-bladder. They project into the duct in regular succession, and are directed obliquely round the tube, presenting much the appearance of a continuous spiral valve (*valvula spiralis* [*Heisteri*]) (Fig. 953). When the duct is distended, the spaces between the folds are dilated, so as to give to its exterior a sacculated appearance.

The **Ductus Communis Choledochus** or **Common Bile-duct** (*ductus choledochus*) Figs. 953 and 954), the largest of the three, is the common excretory duct of the liver and gall-bladder. It is about three inches in length, is of the diameter of a goose-quill, and is formed by the junction of the cystic and hepatic ducts.

It descends within the two layers and along the right border of the lesser omentum behind the first portion the duodenum, in front of the portal vein, and to the right of the hepatic artery (Fig. 859); then passes either between the pancreas and descending portion of the duodenum, or through the head of the pancreas. In fifty-eight dissections Prof. Büngner found that it passed through the pancreas fifty-five times and over the head only three times. Even when it passes through the pancreas it almost always joins the pancreatic duct *outside* of the gland. It descends by the right side of the pancreatic duct and passes with it obliquely through the wall of the descending portion of the duodenum between the mucous and muscular coats in the submucous tissue for one-half to three-

quarters of an inch. The two ducts usually unite just before opening into the duodenum (Figs. 954, 955, and 957), but may remain independent throughout. The **ampulla of Vater** (Fig. 954) is the cavity formed by the fusion of the two ducts, and is much larger than the opening on the bile-papilla. The two ducts open by a common orifice, or by two separate orifices, upon the summit of a papilla, situated at the inner side of the descending portion of the duodenum, a little below its middle and about three or four inches below the pylorus. The muscle of the common duct has a certain amount of sphincter power (Fig. 955), which serves to prevent the entrance of duodenal contents through the small aperture, but is not sufficiently powerful to prevent the flow of bile and pancreatic juice.

Structure.—The coats of the large biliary ducts are an **external** or **fibrous** and an **internal** or **mucous**. The fibrous coat is composed of strong fibro-areolar tissues,

FIG. 956.—Part of the bile-duct and the pancreatic ducts. *C* and *B*, calculi; *Sa*, Santorini's duct; *P*, pancreatic duct; *III* and *IV*, ducts from the right and left lobes of the liver; *II*, cystic duct; *C*, gall-bladder; *A*, common duct. (Byron Robinson.)

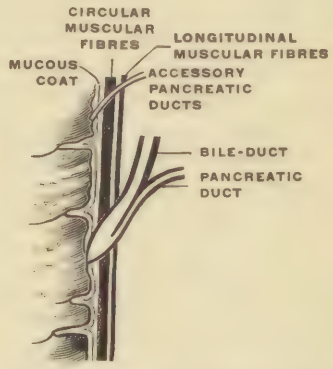

FIG. 957.—Diagram showing the bile and pancreatic ducts piercing the wall of the duodenum obliquely. (Cunningham.)

with a certain amount of muscular tissue arranged, for the most part, in a circular manner around the duct. The mucous coat is continuous with the lining membrane of the hepatic ducts and gall-bladder, and also with that of the duodenum; and, like the mucous membrane of these structures, its epithelium is of the columnar variety. It is provided with numerous mucous glands, which are lobulated and open by minute orifices scattered irregularly in the larger ducts. It is questionable if the smallest biliary ducts, which lie in the interlobular spaces, have any coats. Heidenhain thinks they have a connective-tissue coat, in which are muscle-cells arranged both circularly and longitudinally, and an epithelial layer, consisting of short columnar cells.

Dimensions of the Bile-ducts.—The hepatic duct is about two inches in length, and its lumen is one-sixth of an inch in diameter. The cystic duct is about one and one-half inches in length, and its lumen one-twelfth of an inch in diameter. The common duct is about three inches in length, and its lumen is one-quarter of an inch in diameter. The duodenal opening is smaller than the common duct. The ducts are capable of considerable distention, but the duodenal opening cannot be dilated (Hyrtl).

Blood-vessels, Lymphatics and Nerves of the Gall-bladder and Bile-ducts.—The **cystic artery** (Fig. 418), a branch from the right division of the hepatic, supplies the gall-bladder and cystic duct with blood. It passes along the cystic duct, and on reaching the gall-bladder divides into an upper branch and a lower branch. The upper branch lies between the gall-bladder and the liver and sends branches to each. The lower branch is between the peritoneum and the wall of the gall-bladder. The **cystic veins** empty into the portal vein. The common duct receives branches from the **superior pancreatico-duodenal artery.** There is a **submucous lymphatic network** and a **muscular lymphatic network.** The lymphatics are much less numerous at the fundus of the gall-bladder than at the neck or in the extra-hepatic ducts. The collecting trunks (Fig. 506) end in **glands** along the cystic and common ducts, and these glands are in communication with the duodenal lymphatics and the lymphatics from the head of the pancreas. The **nerves** of the gall-bladder and bile-ducts come from the **coeliac plexus** of the sympathetic. The adjacent peritoneum is plentifully supplied with nerves (Byron Robinson).

The Bile (*fel*).—The bile is a reddish-brown or greenish fluid. It contains pigments (bilirubin and biliverdin), fats and soaps, cholesterin, sodium salts of glycocholic and taurocholic acid, lecithin, and nucleo-albumin furnished by the mucous membrane. There are also present CO_2; chlorides, carbonates, phosphates, and sulphates of the alkalies and of calcium, and iron. The amount normally secreted is from one pint to one and one-half pints in the twenty-four hours.

Surface Relations.—The liver is situated in the right hypochondriac and the epigastric regions, and is moulded to the arch of the Diaphragm. In the greater part of its extent it lies under cover of the lower ribs and their cartilages, but in the epigastric region it comes in contact with the abdominal wall, in the subcostal angle. The *upper limit of the right lobe of the liver* may be defined in the middle line by the junction of the mesosternum with the ensiform cartilage; on the right side the line must be carried upward as far as the fifth rib cartilage in the line of the nipple and then downward to reach the seventh rib at the side of the chest. The *upper limit of the left lobe* may be defined by continuing this line to the left with an inclination downward to a point about two inches to the left of the sternum on a level with the sixth left costal cartilage. The *lower limit of the liver* may be indicated by a line drawn half an inch below the lower border of the thorax on the right side as far as the ninth right costal cartilage, and thence obliquely upward across the subcostal angle to the eighth left costal cartilage. A slight curved line with its convexity to the left from this point—*i. e.*, the eighth left costal cartilage—to the termination of the line indicating the upper limit will denote the left margin of the liver. The fundus of the gall-bladder approaches the surface behind the anterior extremity of the ninth costal cartilage, close to the outer margin of the Right rectus muscle.

It must be remembered that the liver is subject to considerable alterations in position, and the student should make himself acquainted with the different circumstances under which this occurs, as they are of importance in determining the existence of enlargement or other diseases of the organ.

Its position varies according to the posture of the body. In the erect position in the adult male the edge of the liver projects about half an inch below the lower edge of the right costal cartilages, and its anterior border can be often felt in this situation if the abdominal wall is thin. In the supine position the liver gravitates backward and recedes above the lower margin of the ribs, and cannot then be detected by the finger. In the prone position it falls forward, and can then generally be felt in a patient with loose and lax abdominal walls. Its position varies also with the ascent or descent of the Diaphragm. In a deep inspiration the liver descends below the ribs; in expiration it is raised behind them. Again, in emphysema, where the lungs are distended and the Diaphragm descends very low, the liver is pushed down; in some other diseases, as phthisis, where the Diaphragm is much arched, the liver rises very high up. Pressure from without, as in tight lacing, by compressing the lower part of the chest, displaces the liver considerably, its anterior edge often extending as low as the crest of the ilium; and its convex surface is often at the same time deeply indented from the pressure of the ribs. Again, its position varies greatly according to the greater or less distention of the stomach and intestines. When the intestines are empty the liver descends in the abdomen, but when they are distended it is pushed upward. Its relations to surrounding organs may also be changed by the growth of tumors or by collections of fluid in the thoracic or abdominal cavities.

Surgical Anatomy.—*Movable liver* or *hepatoptosis* is a rare condition, in which the liver moves or can be moved from its normal position. It is due to lessened tone of the abdominal

muscles and relaxation of the liver supports. In movable liver the organ may be rotated on its vertical axis or on its transverse axis. Tongue-like lobes have been referred to. On account of its large size, its fixed position, and its friability, the liver is more frequently *ruptured* than any of the abdominal viscera. The rupture may vary considerably in extent, from a slight scratch to an extensive laceration completely through its substance, dividing it into two parts. Sometimes an *internal rupture* without laceration of the peritoneal covering takes place, and such injuries are most susceptible of repair; but small tears of the surface may also heal; when, however, the laceration is extensive, death usually takes place from hemorrhage, on account of the fact that the hepatic veins are contained in rigid canals in the liver-substance and are unable to contract, and are moreover unprovided with valves. The liver may also be torn by the end of a broken rib perforating the Diaphragm. The liver may be injured by *stabs* or other *punctured wounds*, and when these are inflicted through the chest-wall both pleural and peritoneal cavities may be opened up and both lung and liver be wounded. In cases of *wound of the liver* from the front, protrusion of a part of this viscus may take place, but can generally easily be replaced. In cases of laceration of the liver, when there is evidence that bleeding is going on, the abdomen must be opened, the laceration sought for, and the bleeding arrested. This may be done temporarily by introducing the forefinger into the foramen of Winslow and placing the thumb on the gastro-hepatic omentum and compressing the hepatic artery and portal vein between the two. Any bleeding points can then be seen. Bleeding is, if possible, arrested by suture ligatures. The edges of a small laceration are simply brought together and sutured by means of a blunt, curved, round needle passed from one side of the wound to the other. All sutures must be passed before any are tied, and this must be done with the greatest gentleness, as the liver substance is very friable. If suture fails the actual cautery may succeed. When the laceration is extensive, the liver is sutured to the abdominal wall to hold it firm when pressure is applied, and then the laceration is packed with a piece of iodoform gauze, the end of which is allowed to hang out of the external wound. *Abscess of the liver* is of not infrequent occurrence, and may open in many different ways on account of the relations of this viscus to other organs. Thus it may burst into the lung, the pus being coughed up, or into the stomach; the pus perhaps being vomited, it may burst into the colon or into the duodenum, or, by perforating the Diaphragm, it may empty itself into the pleural cavity. Frequently it makes its way forward, and points on the anterior abdominal wall, and finally it may burst into the peritoneal or pericardiac cavity. Abscesses of the liver require opening, and this must be done by an incision in the abdominal wall, in the thoracic wall, or in the lumbar region, according to the direction in which the abscess is tracking. The incision through the abdominal wall is to be preferred when possible. The abdominal wall is incised over the swelling, and unless the peritoneum is adherent, gauze is packed all around the exposed liver surface and the abscess opened, if deeply seated, preferably by the thermo-cautery. *Hydatid cysts* are more often found in the liver than in any other of the viscera. The reason of this is not far to seek. The embryo of the egg of the tænia echinococcus being liberated in the stomach by the disintegration of its shell, bores its way through the gastric walls and usually enters a blood-vessel, and is carried by the blood-stream to the hepatic capillaries, where its onward course is arrested, and where it undergoes development into the fully formed hydatid. *Tumors of the liver* have recently been subjected to surgical treatment by removal of a portion of the organ. The abdomen is opened and the diseased portion of liver exposed; the circulation is controlled by compressing the portal vein and the hepatic artery in the gastro-hepatic omentum and a wedge-shaped portion of liver containing the tumor removed; the divided vessels are ligated and the cut surfaces brought together and sutured in the manner directed above.

When the *gall-bladder* or one of its main ducts is *ruptured*, which may occur independently of laceration of the liver, death usually occurs from peritonitis. If the symptoms have led to the performance of a laparotomy and a small rent is found, it should be sutured; if an extensive opening is found the gall-bladder should be removed. If the cystic duct is torn, its intestinal end must be closed and the gall-bladder removed. In rupture of either of the other ducts, simply provide for free drainage.

The gall-bladder may become distended with bile in cases of *obstruction of its duct* or of the *common bile-duct*, or it may become distended from a collection of *gall-stones* within its interior, thus forming a large tumor. The swelling due to distention with bile is pear-shaped, and projects downward and forward to the umbilicus. It moves with respiration, since it is attached to the liver. To relieve a patient of *gall-stones*, the gall-bladder must be opened and the gall-stones removed. The operation is performed by an incision two or three inches long in the right semilunar line, commencing at the costal margin. The peritoneal cavity is opened, and, the tumor having been found, gauze pads are packed around it to protect the peritoneal cavity, and it is aspirated. When the contained fluid has been evacuated the flaccid bladder is drawn out of the abdominal wound and its wall incised to the extent of an inch; any gall-stones in the bladder are now removed and the interior of the sac sponged dry. If the case is one of obstruction of the duct, an attempt must be made to dislodge the stone by manipulation through the wall of the duct; or it may be crushed from without by the fingers or carefully padded forceps. If this does not succeed, the safest plan is to incise the duct, extract the stone, close

the incision in the duct by fine sutures in two layers and employ drainage. After all obstruction has been removed, four courses are open to the surgeon: 1. The wound in the gall-bladder may be at once sewed up, the organ returned into the abdominal cavity, and the external incision closed. 2. The edges of the incision in the gall-bladder may be sutured to the fascia of the external wound, and a fistulous communication established between the gall-bladder and the exterior; this fistulous opening usually closes in the course of a few weeks. 3. The gall-bladder may be connected with the intestinal canal, preferably the duodenum, by means of a lateral anastomosis; this is known as *cholecystenterostomy*. 4. The gall-bladder may be completely removed (*cholecystectomy*). Plan 2 is usually followed. Plan 4 is employed when the coats of the gall-bladder are seriously diseased. Plan 2 is employed in obstruction of the common duct by malignant disease.

If a stone blocks the diverticulum of Vater and if the common bile-duct and the pancreatic duct empty into the diverticulum, it is evident that both ducts will be blocked. It has been demonstrated that in such a case the pressure urging the bile onward is sufficient to overcome the pressure in the pancreatic duct and drive bile into the ducts of the pancreas, the result, perhaps, being disastrous inflammation of the pancreas.

Septic trouble arises more rapidly when a stone is blocked in the duct than when stones merely block the gall-bladder, because the first-named part is richer in lymphatics (Murphy).

THE PANCREAS (Figs. 958, 959, 960, 961).

Dissection.—The pancreas may be exposed for dissection in three different ways: 1. By raising the liver, drawing down the stomach, and tearing through the gastro-hepatic omentum and the ascending layer of the transverse mesocolon. 2. By raising the stomach, the arch of the colon, and great omentum, and then dividing the inferior layer of the transverse mesocolon and raising its ascending layer. 3. By dividing the two layers of peritoneum, which descend from the great curvature of the stomach to form the great omentum; turning the stomach upward, and then cutting through the ascending layer of the transverse mesocolon (see Fig. 853).

The Pancreas (*παν-κρέας, all flesh*) is a compound racemose gland, analogous in its structure to the salivary glands, though softer and less compactly arranged than those organs. It is long and irregularly prismatic in shape, and has been compared to a human or a dog's tongue; it is of reddish-white color. Its right extremity being broad, is called the **head.** The right half of the head above is continuous with the *neck*, which connects the head to the main portion of the organ, the **body.** The **neck** is a slight constriction or thin part of the gland, placed in front of the portal vein, and connecting the head to the body. The left half of the head is separated from the neck by a notch, the **incisura pancreaticus.** The body of the gland gradually tapers into an extremity directed to the left, and called the **tail.** The pancreas is placed transversely across the posterior wall of the abdomen, at the back of the epigastric and left hypochondriac regions. Its length varies from five to six inches, its breadth is an inch and a half, and its thickness from half an inch to an inch, being greater at its right extremity and along its upper border. Its weight varies from two to three and a half ounces, but it may reach six ounces.

The **Right Extremity** or **Head of the Pancreas** (*caput pancreatis*) (Fig. 958) is shaped like the head of a hammer, being elongated both above and below; it is flattened from before backward, and conforms to the whole concavity of the duodenum, which is slightly overlapped by it. The anterior surface near its left border exhibits a notch, the **incisura pancreatis**, which contains the superior mesenteric vessels. The notch marks the separation of the inferior portion of the head, which is known as the **uncinate process of Winslow** (*processus uncinatus* [*Winslowi*]), which rests, below, upon the inferior portion of the duodenum, and, above, is pushed up back of the upper portion. The lower end of the head is crossed by the transverse colon and its mesocolon. Behind, the head of the pancreas is in relation with the inferior vena cava, the left renal vein, the right crus of the Diaphragm, and the aorta. The common bile-duct descends behind, between the duodenum and pancreas, or in the substance of the gland; and the pan-

creatico-duodenal artery descends in front between the same parts. The head of the pancreas is closely adherent to the duodenum.

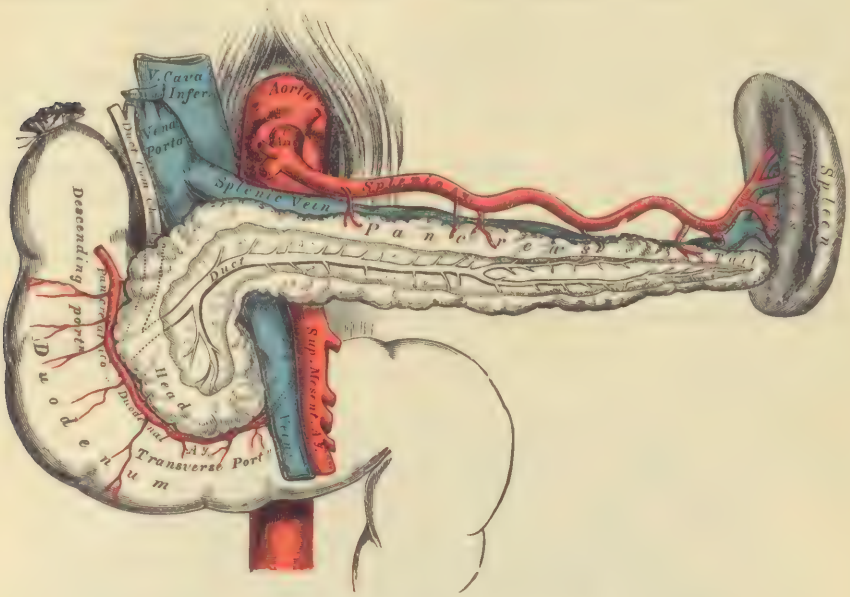

FIG. 958.—The pancreas and its relations.

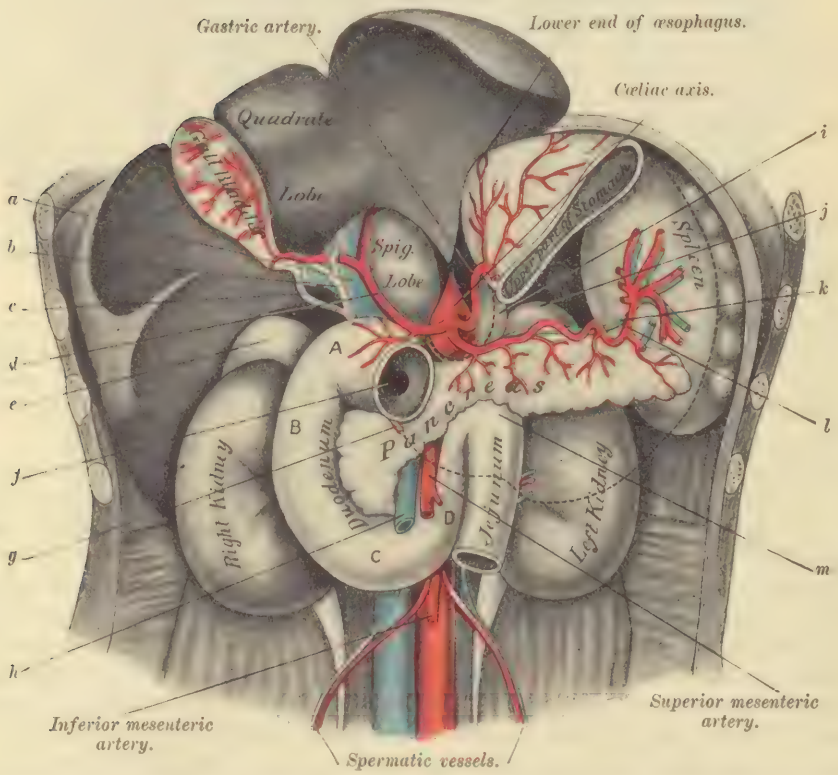

FIG. 959.—The duodenum and pancreas. The liver has been lifted up and the greater part of the stomach removed: *a*, portal vein; *b*, hepatic duct; *c*, cystic duct; *d*, hepatic artery; *e*, right suprarenal capsule; *f*, pyloric orifice; *g*, right gastro-epiploic artery; *h*, superior mesenteric vein; *i*, left crus of diaphragm; *j*, left suprarenal capsule; *k*, splenic vein; *l*, splenic artery; *m*, duodeno-jejunal junction; A, B, C, D, the four portions of the duodenum. (Testut.)

The **Neck of the Pancreas** is about an inch long, and passes upward and forward to the left, having the first part of the duodenum above it, and the termination of the fourth portion below. It lies in front of the commencement of the portal vein, and is grooved on the right by the gastro-duodenal and superior pancreatico-duodenal arteries. The pylorus lies just above it.

The **Body** (*corpus pancreatis*) and **Tail** (*cauda pancreatis*) **of the Pancreas** are somewhat prismatic in shape, and have three surfaces: **anterior, posterior,** and **inferior.**

The Anterior Surface (*facies anterior*).—The anterior surface is somewhat concave, and is covered by the posterior surface of the stomach which rests upon it, the two organs being separated by the lesser sac of the peritoneum. At its right extremity there is a well-marked prominence, called by His the **omental tuberosity** (*tuber omentale*).

The Posterior Surface (*facies posterior*).—The posterior surface is separated from the vertebral column by the aorta, the splenic vein, the left kidney and its vessels, the left suprarenal capsule, the pillars of the Diaphragm, and the origin of the superior mesenteric artery.

The Inferior Surface (*facies inferior*) (Fig. 959).—The inferior surface is narrow, and lies upon the duodeno-jejunal flexure and on some coils of the jejunum; its left extremity rests on the splenic flexure of the colon.

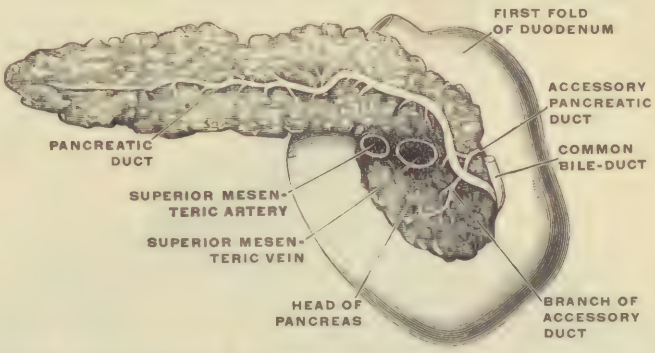

FIG. 960.—The pancreas and duodenum from behind, with the pancreatic duct exposed. The superior mesenteric vessels are also shown in section, passing forward, surrounded by the recurved portion of the head of the pancreas. (Cunningham.)

The Superior Border (*margo superior*) (Fig. 959).—The superior border of the body is blunt and flat to the right; narrow and sharp to the left, near the tail. It commences to the right in the omental tuberosity, and is in relation with the coeliac axis, from which the hepatic artery courses to the right just above the gland, while the splenic branch runs in a groove along this border to the left.

The Anterior Border (*margo anterior*).—The anterior border is the position where the two layers of the transverse mesocolon separate; the one passing upward in front of the anterior surface, the other backward below the inferior surface (Fig. 853).

The **lesser end** or **tail of the pancreas** is narrow; it extends to the left as far as the lower part of the inner aspect of the spleen, and its end is directed upward and to the left (Fig. 959).

Birmingham describes the body of the pancreas as projecting forward as a prominent ridge into the abdominal cavity and forming a sort of shelf on which the stomach lies. He says: "The portion of the pancreas to the left of the middle line has a very considerable antero-posterior thickness; as a result the anterior surface is of considerable extent, it looks strongly upward, and forms a large and important part of the shelf. As the pancreas extends to the left toward the spleen it crosses the upper part of the kidney, and is so moulded on to it that the top of the kidney

forms an extension inward and backward of the upper surface of the pancreas and extends the bed in this direction. On the other hand, the extremity of the pancreas comes in contact with the spleen in such a way that the plane of its upper surface runs with little interruption upward and backward into the concave gastric surface of the spleen, which completes the bed behind and to the left, and, running upward, forms a partial cap for the wide end of the stomach."[1] An occasional anomaly is a pancreas prolonged in front of the duodenum or actually embracing it (annular pancreas).

Peritoneal Relations (Fig. 853).—The transverse mesocolon is attached to the anterior border of the pancreas, from the tail to the neck of the gland, and the two layers of the mesocolon separate. The anterior layer which comes from the lesser peritoneum covers part of the anterior surface and the superior surface; the posterior layer, which comes from the greater omentum, covers the rest of the anterior surface and the inferior surface. The posterior surface is devoid of peritoneum.

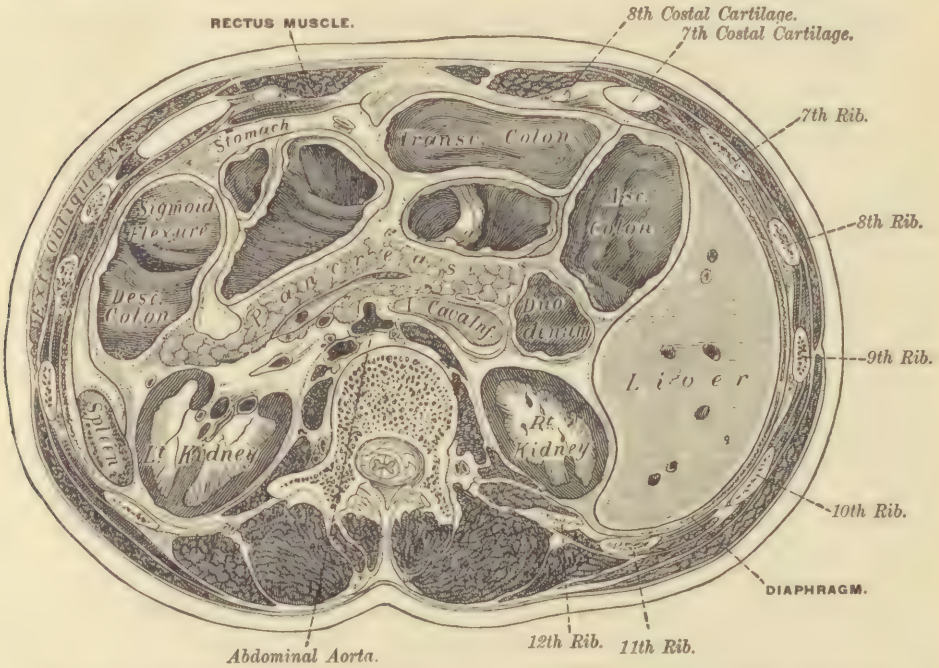

FIG. 961.—Transverse section through the middle of the first lumbar vertebra, showing the relations of the pancreas. (Braune.)

There is in front of the head and at the anterior margin a narrow strip of pancreas, which remains uncovered by peritoneum and which corresponds to the cellular tissue of the mesocolon.

The principal excretory duct of the pancreas, called the **pancreatic duct** or **canal of Wirsung** (*ductus pancreaticus* [*Wirsungi*]) (Figs. 956, 958, and 960), from its discoverer, extends transversely from left to right through the substance of the pancreas. In order to expose it, the superficial portion of the gland must be removed. It commences by the junction of the small ducts of the lobules situated in the tail of the pancreas, and, running from left to right through the body, it constantly receives the ducts of the various lobules composing the gland. Considerably augmented in size, it reaches the neck, and turning obliquely downward, backward, and to the right, it comes into relation with the common bile-duct, lying to

[1] Journal of Anatomy and Physiology, vol. xxxi. part i. p. 102.

its left side; leaving the head of the gland, it passes very obliquely through the mucous and muscular coats of the duodenum, and usually terminates by an orifice common to it and the ductus communis choledochus upon the summit of an elevated papilla, situated at the inner side of the descending portion of the duodenum, three or four inches below the pylorus (Figs. 954, 955, and 957).

Sometimes the pancreatic duct and ductus communis choledochus open separately into the duodenum (Fig. 893). In about one-fifth of the subjects there is an accessory duct, which is given off from the canal of Wirsung in the neck of the pancreas and passes horizontally to the right to open into the duodenum about an inch above the orifice of the main duct. This is known as the **duct of Santorini** (*ductus pancreaticus accessorius* [*Santorini*]) (Figs. 956, 957, and 960).

The pancreatic duct, near the duodenum, is about the size of an ordinary quill; its walls are thin, consisting of two coats, an external fibrous and an internal mucous; the latter is smooth, and furnished near its termination with a few scattered follicles.

Structure.—In structure, the pancreas resembles the salivary glands. It differs from them, however, in certain particulars, and is looser and softer in its texture. It is not enclosed in a distinct capsule, but is surrounded by areolar tissue, which dips into its interior, and connects together the various lobules of which it is composed. Each lobule, like the lobules of the salivary glands, consists of one of the ultimate ramifications of the main duct, terminating in a number of caecal pouches or alveoli, which are tubular and somewhat convoluted. The minute ducts connected with the alveoli are narrow and lined with flattened cells. They are the secreting end tubules. The narrow ducts which come from the end tubules are lined with flat epithelial cells. The alveoli are almost completely filled with secreting cells, so that scarcely any lumen is visible. In the centre of the end tubules flat cells are frequently found. They are continuations into the tubules of the duct epithelium. These cells are known as the **centro-acinar cells of Langerhans.** The true secreting cells which line the wall of the alveolus are very characteristic. They are columnar or rounded in shape and present two zones: an outer one clear and finely striated next the basement-membrane, and an inner granular one next the lumen. The highly refracting granules are known as **zymogen granules.** During digestion the granules gradually disappear and the cells become clear. During fasting the granular zone occupies more than one-half of the cell (Szymonowicz). In some secreting cells of the pancreas is a spherical mass, staining more easily than the rest of the cells; this is termed the **paranucleus,** and is believed to be an extension from the nucleus. The connective tissue among the gland tubules and alveoli presents in certain parts collections of cells, which are termed **inter-alveolar cell-islets, intertubular cell-masses** or **islands of Langerhans.** Opie points out that they are most common in the splenic end of the pancreas. The cells of the islands are smaller than the secreting cells of the alveoli, and are arranged in layers with intervening spaces. The islands are surrounded by fine connective tissue. The spaces in the islands contain capillaries. There are no ducts in the islands of Langerhans. Their function is to furnish the internal secretion of the pancreas.

Blood-vessels, Lymphatics, and Nerves.—The **arteries of the pancreas** come from the **superior pancreatico-duodenal branch of the gastro-duodenal**; the **inferior pancreatico-duodenal branch of the superior mesenteric**; the **inferior pancreatic branch of the superior mesenteric**; **pancreatic branches of the hepatic** and **pancreatic branches of the splenic.** In a few cases a large artery, the **pancreatica magna,** accompanies the pancreatic duct. In most cases there is no such vessel. The **veins** are the **anterior pancreatico-duodenal branch of the superior mesenteric**; the **posterior pancreatico-duodenal branch** and other **pancreatic branches of the portal**; and **pancreatic branches of the splenic.** The **lymphatics** arise in a network about the lobules.

Numerous collecting trunks pass to the surface of the pancreas, anastomose with each other, and enter into glands about the pancreas. The **splenic glands** receive most of the trunks. Others are received by glands along the aorta (Sappey), glands at the origin of the superior mesenteric artery, and glands along the pancreatico-duodenal vessels.[1] The **nerves** come from the **coeliac, superior mesenteric,** and **splenic plexuses.**

The Pancreatic Juice.—The pancreatic juice is a clear, somewhat viscid alkaline liquid. Its specific gravity is about 1030. The solid matter consists chiefly of proteids, and amounts to about 10 per cent. of a sample of the juice.[2] The juice contains a ferment which breaks up fat, a ferment which converts starch into sugar, a ferment which curdles milk, and a ferment which digests proteid material.

Surface Form.—The pancreas lies in front of the second lumbar vertebra, and can sometimes be felt, in emaciated subjects, when the stomach and colon are empty, by making deep pressure in the middle line about three inches above the umbilicus.

Surgical Anatomy.—Of late years our knowledge of the structure, functions, and diseases of the pancreas has been notably increased, and surgeons have begun to operate for certain pancreatic diseases. It is occasionally the seat of *cancer*, which usually affects the head or duodenal end, and therefore often speedily involves the common bile-duct, leading to persistent jaundice. Cancer of the pancreas may be primary or secondary. *Primary sarcoma* is very unusual; secondary sarcoma is more common, but cancer is far commoner than either form of sarcoma. *Adenoma* may also occur. Cases are on record of the successful removal of tumors of the pancreas, but the operations are very dangerous, are extremely difficult, and are seldom attempted. The pancreas may be the seat of *syphilitic* or *tuberculous disease*. As a result of pancreatic injury, there may be *effusion into the lesser peritoneal cavity*. The lesser cavity becomes distended, and the fluid of this *pseudo-cyst* may contain pancreatic juice (Jordan Lloyd). True *cysts* of the pancreas are occasionally found. Pancreatic cysts may result from blocking of the duct, from epithelial proliferation, from traumatism and hemorrhage, or from hydatid disease. *Congenital cysts* may occur, and *cystic carcinoma* is sometimes encountered. Cysts of the pancreas may present in the epigastric region above and to the right of the umbilicus. The fluid in these cysts contains some of the pancreatic secretion. A pancreatic cyst is best treated by opening the abdomen, suturing the cyst to the skin, opening the cyst and providing for drainage. Complete extirpation of the cyst is invariably difficult and is usually impossible. It has been said that the pancreas is the only abdominal viscus which has never been found in a hernial protrusion; but even this organ has been found, in company with other viscera, in rare cases of *diaphragmatic hernia*. The pancreas has been known to become invaginated into the intestine, and portions of the organ have sloughed off. In cases of *excision of the pylorus* great care must be exercised to avoid wounding the pancreas, as the escape of the pancreatic fluid may be attended with serious and even with fatal results, peritonitis and *fat necrosis*, and gangrene being caused.

Rupture of the pancreas as a solitary result of traumatism is very unusual, but is more common in violent injuries which rupture the liver and spleen as well. An injury which lacerates the pancreas and permits blood and pancreatic juice to flow into the lesser peritoneal cavity is usually rapidly fatal, but may not be. The foramen of Winslow may be occluded by inflammation, and a pseudo-cyst may form. In severe laceration of the pancreas alone, it would be proper to open the abdomen, ligature bleeding vessels, suture the pancreas, and drain the lesser peritoneal cavity posteriorly. A *gunshot wound of the pancreas* requires posterior drainage. Every effort must be made in a pancreatic wound to rapidly get rid of pancreatic fluid by drainage from the wound area, as this fluid is extremely irritant and may cause gangrene.

Inflammation of the pancreas is due to infection. Occasionally it seems to follow the entrance of bile into the pancreatic duct, because of plugging of the ampulla with a calculus (Halsted, Opie). Hemorrhage into the pancreas is frequent in acute pancreatitis, and fat necrosis is common in the fat of the mesentery, subperitoneal tissue, omentum, and other parts. Acute pancreatitis may be recovered from if the abdomen is opened, the pancreas incised, and drainage employed.

In *chronic interstitial pancreatitis* of the head of the pancreas the gall-duct is apt to become blocked, and the disease is frequently mistaken for cancer. Cure may follow opening and drainage of the gall-bladder.

THE SPLEEN (LIEN) (Figs. 958. 959, 961).

The spleen belongs to that class of bodies which are known as **ductless glands.** It is probably related to the blood-vascular system, but in consequence of its

[1] Poirier, Cunéo, and Delamare on the Lymphatics. Edited and translated by Cecil H. Leaf.
[2] Robson and Moynihan on Diseases of the Pancreas.

anatomical relationship to the stomach and its physiological relationship to the liver it is convenient to describe it in this section. It is situated principally in the posterior portion of the left hypochondriac region, its upper and inner extremity extending into the epigastric region; lying between the fundus of the stomach and the Diaphragm. If the abdomen is opened a spleen of ordinary size is not visible from the front, as it is placed between the left kidney, Diaphragm, and stomach. It moves with the respiratory movements and with the movements of the stomach. It is the largest of the so-called **ductless glands**, and varies greatly in size. Usually it measures some five inches in length. It is of an oblong, flattened form, soft, of very brittle consistence, highly vascular, and of a dark-purplish color.

Surfaces. **The External or Phrenic Surface** (*facies diaphragmatica*).—The external or phrenic surface is convex, smooth, and is directed upward, backward, and to the left, except at its upper end, where it is directed slightly inward. It is in relation with the under surface of the Diaphragm, which separates it from the eighth, ninth, tenth, and eleventh ribs of the left side, and in part from the lower border of the left lung and pleura. It is to be remembered that not only are the peritoneum and the Diaphragm between the spleen and the ribs, but also the cavity of the left pleura and a portion of the left lung.

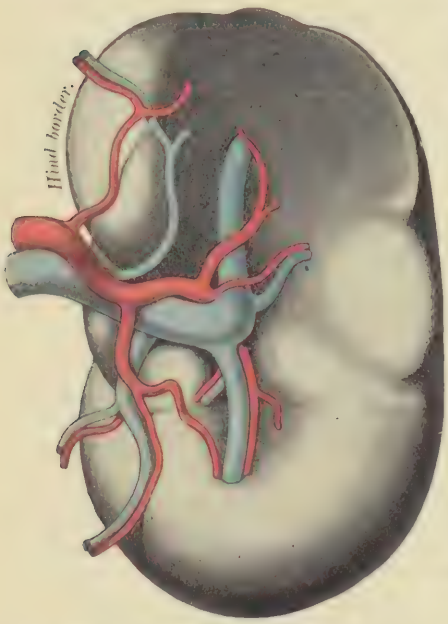

FIG. 962. The spleen, showing its gastric and renal surfaces. (Testut.)

The Internal Surface.—The internal surface is concave, and divided by a ridge into an **anterior** or **larger**, and a **posterior** or **smaller portion**.

The **Anterior Portion** of the internal surface or the **gastric surface** (*facies gastrica*), which is directed forward and inward, is broad and concave, and is in contact with the posterior wall of the great end of the stomach; and below this with the tail of the pancreas. It presents near its inner border a long fissure, termed the **hilum** (*hilus lienis*). This is pierced by several irregular apertures, for the entrance and exit of vessels and nerves.

The **Posterior Portion** of the internal surface or the **renal surface** (*facies renalis*) is directed inward and downward. It is somewhat flattened, does not reach as high as the gastric surface, is considerably narrower than the latter, and is in relation with the upper part of the outer surface of the left kidney and occasionally with the left suprarenal capsule.

The **upper end of the spleen** (*extremitas superior*) is directed inward, toward the vertebral column, where it lies on a level with the eleventh dorsal vertebra. The **lower end** (*extremitas inferior*), sometimes termed the **basal surface**, is flat, triangular in shape, and rests upon the splenic flexure of the colon and the phreno-colic ligament, and is generally in contact with the tail of the pancreas. The **anterior border** (*margo anterior*) is free, sharp, and thin, and is often notched, especially below. It separates the phrenic surface from the gastric surface. The **posterior border** (*margo posterior*) is more rounded and blunter than the anterior. It separates the renal portion of the internal surface from the phrenic surface. It corresponds to the lower border of the eleventh rib and lies between the Diaphragm and left kidney.

The **internal border** is the name sometimes given to the ridge which separates the renal and gastric portions of the internal surface.

The spleen is surrounded by peritoneum, except at the hilum and the serous membrane, is firmly adherent to its capsule, and is held in position by two folds of this membrane: one, the **lieno-renal ligament** (*ligamentum phrenicolienale*) (Figs. 857 and 860), is derived from the layers of peritoneum forming the greater and lesser sacs, where they come into contact between the left kidney and the spleen. Between its two layers the splenic vessels pass; the second, the **gastro-splenic omentum** (*ligamentum gastrolienale*), also formed of two layers, derived from the greater and lesser sacs, respectively, where they meet between the spleen and stomach (Fig. 860). Between these two layers run the vasa brevia of the splenic artery and vein. The spleen is also supported by the **phreno-colic ligament** (*ligamentum phrenicocolicum*), upon which its lower end rests.

The size and weight of the spleen are liable to very extreme variations at different periods of life, in different individuals, and in the same individual under different conditions. *In the adult*, in whom it attains its greatest size, it is usually

FIG. 963.—Transverse section of the spleen, showing the trabecular tissue and the splenic vein and its tributaries.

about five inches in length, three inches in breadth, and an inch or an inch and a half in thickness, and weighs about seven ounces. *At birth*, its weight, in proportion to the entire body, is almost equal to what is observed in the adult, being as 1 to 350; while in the adult it varies from 1 to 320 to 1 to 400. *In old age*, the organ not only decreases in weight, but decreases considerably in proportion to the entire body, being as 1 to 700. The size of the spleen is increased during and after digestion, and varies considerably according to the state of nutrition of the body, being large in highly fed, and small in starved animals. In intermittent and other fevers it becomes much enlarged, weighing occasionally from eighteen to twenty pounds.

Frequently in the neighborhood of the spleen, and especially in the gastro-splenic and great omenta, small nodules of splenic tissue may be found, either isolated, or connected to the spleen by thin bands of splenic tissue. Every such nodule is known as a **supernumerary** or **accessory spleen** (*lien accessorius*). Accessory spleens vary in size from that of a pea to that of a plum.

Support and Movability of the Spleen.—The spleen is normally movable within certain narrow limits. It moves with respiration and with stomach movements. It is supported by ligaments (p. 1355). An unduly movable spleen is called a **movable spleen.** In order that a spleen shall become unduly movable, the ligaments must stretch, and this stretching is often effected when the organ is greatly enlarged, but even an apparently normal spleen may become movable. Movable spleen is usually associated with movable left kidney.

Structure.—The spleen is invested by two coats—an **external serous** and an **internal fibro-elastic coat.**

The External or Serous Coat (*tunica serosa*).—The external or serous coat is derived from the peritoneum; it is thin, smooth, and in the human subject is intimately adherent to the fibro-elastic coat. It invests the entire organ, except at the places of its reflection on to the stomach and Diaphragm and at the hilum.

The Fibro-elastic Coat (*tunica albuginea*).—The fibro-elastic coat forms the framework of the spleen. It is composed of connective tissue containing muscle-cells and elastic fibres, and it invests the organ as a *capsule*, and at the hilum is reflected inward upon the vessels in the form of sheaths. From these sheaths, as well as from the inner surface of the fibro-elastic coat, numerous small fibrous bands, **trabeculae** (*trabeculae lienis*) (Figs. 963 and 964), are given off in all directions; these uniting, constitute the framework of the spleen. This framework resembles a sponge-like material, consisting of a number of small spaces or areolae formed by the trabeculae, which are given off from the inner surface of the capsule, or from the sheaths prolonged inwardly on the blood-vessels. The spaces or areolae contain the adenoid material known as **splenic pulp** (*pulpa lienis*).

The proper coat, the sheaths of the vessels and the trabeculae, consist of a dense mesh of white and yellow elastic fibrous tissues, the latter decidedly predominating. It is owing to the presence of this tissue that the spleen possesses a considerable amount of elasticity, which allows of the very great variations in size that it presents under certain circumstances. In addition to these constituents of this tunic, there is found in man a small amount of non-striped muscular fibre, and in some mammalia (*e. g.*, dog, pig, and cat) a very considerable amount, so that the trabeculae appear to consist chiefly of muscular tissue. It is probably because of this muscular structure that the spleen exhibits, when acted upon by the galvanic current, faint traces of contractility.

The proper substance of the spleen or splenic-pulp is a soft mass of a dark reddish-brown color, resembling grumous blood. When a thin section is examined under a microscope, it is found to consist of a number of branching cells and an intercellular substance. The cells are connective-tissue corpuscles, and have been named the **sustentacular** or **supporting cells of the pulp.** The processes of these branching cells communicate with each other, thus forming a delicate reticulated tissue in the interior of the areolae formed by the trabeculae of the capsule; so that each primary space may be considered to be divided into a number of smaller spaces by the junction of these processes of the branching corpuscles. These secondary spaces contain blood, in which, however, the white corpuscles are found to be in larger proportions than in ordinary blood. The sustentacular cells are either small uni-nucleated or larger multi-nucleated cells; they do not stain deeply with carmine, like the cells of the Malpighian bodies, presently to be described (W. Müller), but like them they possess amœboid movements (Cohnheim). In many of them may be seen deep red or reddish-yellow granules of various sizes which present the characters of the hæmatin of the blood. Sometimes, also, unchanged blood-disks are seen included in these cells, but more frequently blood-disks are found which are altered both in form and color. In fact, blood-corpuscles in all stages of disintegration may be noticed to occur within them. Klein has recently pointed out that sometimes

these cells in the young spleen contain a proliferating nucleus; that is to say, the nucleus is of large size, and presents a number of knob-like projections, as if small nuclei were budding from it by a process of gemmation. This observation is of importance, as it may explain one possible source of the colorless blood-corpuscles.

The interspaces or areolæ formed by the framework of the spleen are thus filled by a delicate reticulum of branched connective-tissue corpuscles, the interstices of which are occupied by blood, and in which the blood-vessels terminate in the manner now to be described.

Blood-vessels of the Spleen.—The **splenic artery** (Fig. 961) is remarkable for its large size in proportion to the size of the organs, and also for its tortuous course. It divides into six or more branches, which enter the hilum of the spleen and ramify throughout its substance, receiving sheaths from the involution of the external fibrous tissue. Similar sheaths also invest the nerves and veins.

Each branch runs in the transverse axis of the organ from within outward, diminishing in size during its transit, and giving off in its passage smaller branches, some of which pass to the anterior, others to the posterior part. These ultimately

FIG. 964.—Transverse section of the human spleen, showing the distribution of the splenic artery and its branches.

leave the trabecular sheaths, and terminate in the proper substance of the spleen in small tufts or pencils of minute arterioles, which open into the interstices of the reticulum formed by the branched sustentacular cells (Figs. 964, 965, and 966). Each of the larger branches of the artery supplies chiefly that region of the organ in which the branch ramifies, having no anastomosis with the majority of the other branches.

The **arterioles** (Fig. 966), supported by the minute trabeculae, traverse the pulp in all directions in bundles or pencilli of straight vessels. Their external coat, on leaving the trabecular sheaths, consists of ordinary connective tissue, but it gradually undergoes a transformation, becomes much thickened, and is converted into a lymphoid material.[1] This change is effected by the conversion of the connective tissue into a lymphoid tissue, the bundles of connective tissue becoming looser and laxer, their fibrils more delicate, and containing in their interstices an abundance of lymph-corpuscles (W. Müller). This lymphoid material is supplied with blood by minute vessels derived from the artery with which they are

[1] According to Klein, it is the sheath of the small vessel which undergoes this transformation, and forms a "solid mass of adenoid tissue which surrounds the vessel like a cylindrical sheath." (Atlas of Histology, p. 424.)

in contact, and which terminates by breaking up into a network of capillary vessels.

The altered coat of the arterioles, consisting of lymphoid tissue (Fig. 966), presents here and there thickenings of a spheroidal shape, the **Malpighian bodies of the spleen** (*noduli lymphatici lienales* [*Malpighii*]) (Fig. 965). These bodies vary in size from about the $\frac{1}{100}$ of an inch to the $\frac{1}{25}$ of an inch in diameter. They are merely local expansions or hyperplasiae of the lymphoid tissue of which the external coat of the smaller arteries of the spleen is formed. They are most frequently found surrounding the arteriole, which thus seems to tunnel them, but occasionally they grow from one side of the vessel only, and present the appearance of a sessile bud growing from the arterial wall. Klein, however, denies this, and says it is incorrect to describe the Malpighian bodies as isolated masses of adenoid tissue, but that they are always formed around an artery, though there is generally a greater amount on one side than on the other, and that, therefore, in transverse sections the artery in the majority of cases is found in an eccentric position. These bodies are visible to the naked eye on the surface of a fresh section of the organ, appearing as minute dots of semi-opaque whitish color in the dark substance of the pulp. In minute structure they resemble the adenoid tissue of lymphatic glands, consisting of a delicate reticulum in the meshes of which lie ordinary lymphoid cells.

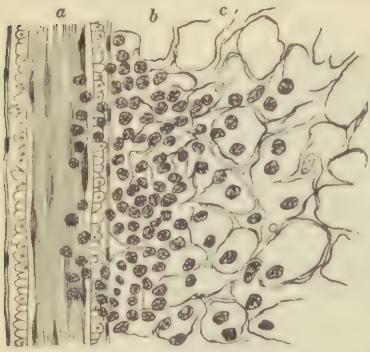

FIG. 965.—Part of a Malpighian body of the spleen of man. *a*, arterial branch in longitudinal section; *b*, adenoid tissue, still containing the lymph-corpuscles; only their nuclei are shown; *c*, adenoid reticulum, the lymph-corpuscles accidentally removed. (Klein and Noble Smith.)

The reticulum of the tissue is made up of extremely delicate fibrils, and is comparatively open in the centre of the corpuscle, becoming closer at the periphery of the body. The cells which it encloses, like the supporting cells of the pulp, are possessed of amœboid movements, but when treated with carmine become deeply stained, and can thus easily be recognized from those of the pulp.

The arterioles terminate in capillaries, which traverse the pulp in all directions; their walls become much attenuated, lose their tubular character, and the cells of the lymphoid tissue of which they are composed become altered; presenting a branched appearance and acquiring processes which are directly connected with the processes of the sustentacular cells of the pulp (Fig. 966). In this manner the capillary vessels terminate, and the blood flowing through them finds its way into the interstices of the reticulated tissue formed by the branched connective-tissue corpuscles of the splenic pulp. Thus the blood passing through the spleen is brought into intimate relation with the elements of the pulp, and no doubt undergoes important changes.

After these changes have taken place the blood is collected from the interstices of the tissue by the rootlets of the veins (Fig. 963), which commence much in the same way as the arteries terminate. Where a vein is about to originate the connective-tissue corpuscles of the pulp arrange themselves in rows in such a way as to form an elongated space or sinus. They become changed in shape, being elongated and spindle-shaped, and overlap each other at their extremities. They thus form a sort of endothelial lining of the path or sinus, which is the radicle of a vein. On the outer surface of these cells are seen delicate transverse lines or markings which are due to minute elastic fibrillae arranged in a circular manner around the sinus. Thus the channel obtains a continuous external investment, and gradually becomes converted into a small vein, which after a time presents a coat of ordinary connective tissue, lined by a layer of fusiform endothelial cells which are

continuous with the supporting cells of the pulp. The smaller veins unite to form larger ones which do not accompany the arteries, but soon enter the trabecular sheaths of the capsule, and by their junction form from six or more branches which emerge from the hilum and, uniting, form the splenic vein, the largest radicle of the portal vein (Figs. 958 and 962).

The **veins** are remarkable for their numerous anastomoses, while the arteries hardly anastomose at all.

The **lymphatics** originate in two ways—*i.e.*, from the sheaths of the arteries and in the trabeculæ. The former trunks are the **deep collecting trunks,** and

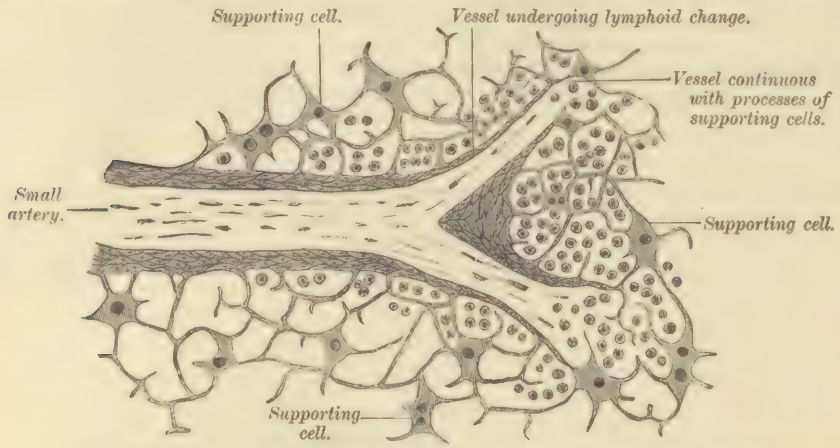

FIG. 966.—Section of spleen, showing the termination of the small blood-vessels.

accompany the blood-vessels; the latter pass to the **superficial lymphatic plexus,** which may be seen on the surface of the organ. The two sets communicate in the interior of the organ. The deep trunks at the hilum number from five to ten, and terminate in the **splenic glands**. The superficial trunks also pass to the hilum and terminate in the splenic glands.

The **nerves** are derived from the **splenic plexus,** which is part of or connected with the solar plexus. The nerves enter the spleen with the vessels.

Surface Form.—The spleen is situated under cover of the ribs of the left side, being separated from them by the Diaphragm, and above by a small portion of the lower margin of the left lung and pleura. Its position corresponds to the eighth, ninth, tenth, and eleventh ribs. It is placed very obliquely. "It is oblique in two directions viz., from above downward and outward, and also from above downward and forward" (Cunningham). "Its highest and lowest points are on a level respectively with the ninth dorsal and first lumbar spines; its inner end is distant about an inch and a half from the median plane of the body, and its outer end about reaches the mid-axillary line" (Quain).

Surgical Anatomy.—Injury of the spleen is less common than that of the liver, on account of its protected situation and connections. It may be *ruptured* by direct or indirect violence, torn by a broken rib, or injured by a punctured or gunshot wound. When the organ is enlarged the chance of rupture is increased. The great risk is *hemorrhage*, owing to the extreme vascularity of the organ, and the absence of a proper system of capillaries. The injury is not, however, necessarily fatal, and this would appear to be due in a great measure to the contractile power of its capsule, which narrows the wound and thus antagonizes the escape of blood. In cases in which the symptoms suggest such an injury and indicate danger to life, laparotomy must be performed; and if the hemorrhage cannot be arrested by ordinary surgical methods the spleen must be removed. The spleen may become displaced, producing great pain from stretching of the vessels and nerves, and this dislocation may render necessary removal of the organ. The spleen may become enormously *enlarged* in certain diseased conditions, such as ague, leukæmia, syphilis, valvular disease of the heart, or without any obtainable history of previous disease. It may also become enlarged in lymphadenoma as a part of a general blood disease. In these cases the mass may fill the abdomen and extend into the pelvis, and may be mistaken for ovarian or uterine disease.

The spleen is sometimes the seat of *cystic tumors*, especially hydatids, and of *abscess*. These cases require treatment by incision and drainage; and in abscess great care must be taken if there are no adhesions between the spleen and abdominal cavity, to prevent the escape of any of the pus into the peritoneal cavity. If possible, the operation should be performed in two stages. *Sarcoma* and *carcinoma* are occasionally found in the spleen, but very rarely as a primary disease. In *movable spleen*, if the organ is normal, follow the advice of Rydygier and loosen the parietal peritoneum to make a pocket, place the spleen in the pocket, and pass sutures through the parietal peritoneum and the splenic ligaments. A movable diseased spleen should be removed.

Extirpation of the spleen has been performed for wounds or injuries, floating spleen, simple hypertrophy, and leukæmic enlargement; but in the latter case the operation is now regarded as unjustifiable, as it is practically certain to terminate fatally. The incision is best made in the left semilunar line: the spleen is isolated from its surroundings, and the pedicle transfixed and ligatured in two portions, before the tumor is turned out of the abdominal cavity, if this is possible, so as to avoid any traction on the pedicle, which may cause tearing of the splenic vein and which inevitably induces grave shock. In applying the ligatures the surgeon must not include the tail of the pancreas, and in lifting out the organ care must be taken to avoid rupturing the capsule.

THE ORGANS OF VOICE AND RESPIRATION.

THE LARYNX.

THE Larynx is the organ of voice, placed at the upper part of the air-passage. It is situated between the trachea and base of the tongue, at the upper and forepart of the neck, where it forms a considerable projection in the middle line. On either side of it lie the great vessels of the neck; behind, it forms part of the boundary of the pharynx, and is covered by the mucous membrane lining that cavity. Its vertical extent corresponds to the fourth, fifth, and sixth cervical vertebrae, but it is placed somewhat higher in the female and also during childhood. In infants between six and twelve months of age Symington found that the tip of

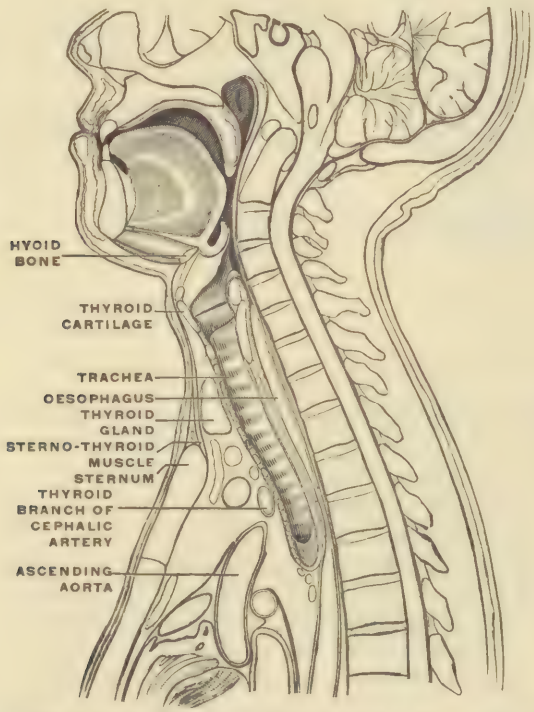

FIG. 967.—Sagittal section of a man twenty-one years of age. (After W. Braune.)

the epiglottis was a little above the level of the cartilage between the odontoid process and body of the axis, and that between infancy and adult life the larynx descends for a distance equal to two vertebral bodies and two intervertebral disks. The movements of the head affect the position of the larynx. When the head is drawn back, the larynx is lifted, and when the chin approaches the chest the larynx is depressed. During swallowing the larynx moves distinctly; during singing it moves slightly. The larynx is suspended by the stylo-hyoid ligament, the

muscles of the upper border of the hyoid bone, the Stylo-pharyngeus and Palato-pharyngeus muscles. According to Sappey, the average measurements of the adult larynx are as follows:

	In males.	In females.
Vertical diameter	44 mm.	36 mm.
Transverse diameter	43 "	41 "
Antero-posterior diameter	36 "	26 "
Circumference	136 "	112 "

Until puberty there is no marked difference between the larynx of the male and that of the female. In the latter its further increase in size is only slight, whereas in the former it is great; all the cartilages are enlarged, and the thyroid becomes prominent as the pomum Adami in the middle line of the neck, while the length of the glottis is nearly doubled.

The larynx is broad above, where it presents the form of a triangular box, flattened behind and at the sides, and bounded in front by a prominent vertical ridge. Below, it is narrow and cylindrical. It is composed of cartilages, which are connected together by ligaments and moved by numerous muscles. It is lined by mucous membrane, which is continuous above with that lining the pharynx and below with that of the trachea.

In the median line of the neck the larynx has in front of it the skin and cervical fascia. There is often a bursa between the skin and fascia over the most prominent part of the larynx. It is called the **bursa subcutanea prominentiae laryngeae**. It is present particularly in men, and is seldom found in the young or in women. The larynx is covered to each side by the thyroid gland, and the Sterno-hyoid, Sterno-thyroid, Thyro-hyoid, and Omo-hyoid muscles, and the Inferior constrictors of the pharynx. Posterior is the laryngeal portion of the pharynx.

The Cartilages of the Larynx (*cartilagines laryngis*).—The cartilages of the larynx are nine in number, three single, and three pairs:

Thyroid.	Two Arytenoid.
Cricoid.	Two Cornicula Laryngis.
Epiglottis.	Two Cuneiform.

The Thyroid Cartilage (*cartilago thyreoidea*) (Figs. 968 and 969).—The thyroid cartilage (from *θυρεός, a shield*) is hyaline cartilage and is the largest cartilage of the larynx. It is at the anterior and upper portion of the larynx. It consists of two lateral **lamellae** or **alae**, united at an acute angle in front, forming a vertical projection in the middle line, which is prominent above and called the **pomum Adami** (*prominentia laryngea*). This projection is subcutaneous, is more distinct in the male than in the female, and is often separated from the integument by a bursa, the **bursa subcutanea prominentiae laryngeae.**

Each lamella is quadrilateral in form. Its *outer surface* (Fig. 968) presents an **oblique ridge** (*linea obliqua*), which passes downward and forward from a tubercle situated near the root of the superior cornu, the **superior tubercle** (*tuberculum thyreoideum superius*), to a small tubercle near the anterior part of the lower border, the **inferior tubercle** (*tuberculum thyreoideum inferius*). This ridge gives attachment to the Sterno-thyroid and Thyro-hyoid muscles, and the portion of cartilage included between it and the posterior border gives attachment to part of the Inferior constrictor muscle. Just below each superior tubercle there is often an opening, the **thyroid foramen** (*foramen thyreoideum*).

The anterior borders of the alae of the thyroid cartilage which are continuous below are separated above by a V-shaped notch, the **thyroid notch** (*incisura thyreoidea* [*superior*]).

The **Inner Surface** (Fig. 969) of each ala is smooth, slightly concave, and covered by mucous membrane above and behind; but in front, in the receding angle formed by their junction, are attached the epiglottis, the true and false vocal cords, the Thyro-arytenoid and Thyro-epiglottidean muscles, and the thyro-epiglottidean ligament.

The **Upper Border** or **Margin of the Thyroid Cartilage** (Fig. 969) is sinuously curved, being concave at its posterior part, just in front of the superior cornu, then rising into a convex outline, which dips in front to form the sides of the thyroid notch, in the middle line, immediately above the pomum Adami. This border gives attachment throughout its whole extent to the **thyro-hyoid** or **hyo-thyroid membrane** (*membrana hyothyreoidea*).

The **Lower Border** or **Margin** (Fig. 969) is nearly straight in front, but behind, close to the cornu, it is concave. It is connected to the cricoid cartilage, in and near the median line, by the middle portion of the **crico-thyroid membrane** (*membrana cricothyreoidea*); and, on either side, by the Crico-thyroid muscle.

The **Posterior Borders** (Fig. 969) are thick and rounded, and each terminates above, in a **superior cornu** (*cornu superius*), and below, in an **inferior cornu** (*cornu inferius*). The two superior cornua are long and narrow, directed upward, backward, and inward, and terminate in conical extremities, which give attachment to the lateral thyro-hyoid ligaments. The two inferior cornua are short and thick; they pass downward, with a slight inclination forward and inward, and each presents on its inner surfaces a small oval articular facet for articulation with the side of the cricoid cartilage (Fig. 968). The posterior border receives the insertion of the Stylo-pharyngeus and Palato-pharyngeus muscles on each side.

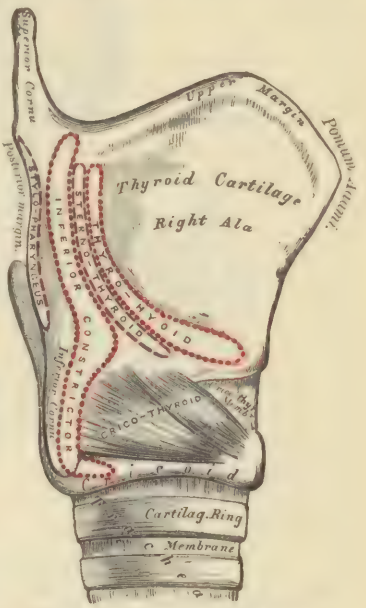

FIG. 968.—Side view of the thyroid and cricoid cartilages.

During infancy the alae of the thyroid cartilage are joined to each other by a narrow, lozenge-shaped strip, named the **intrathyroid cartilage**. This strip extends from the upper to the lower border of the thyroid cartilage in the middle line, and is distinguished from the alae by being more transparent and more flexible.

The Cricoid Cartilage (*cartilago cricoidea*) (Figs. 968, 969, and 971).—The cricoid cartilage is so called from its resemblance to a signet ring (*κρίκος, a ring*). It is smaller, but thicker and stronger than the thyroid cartilage, and forms the lower and back part of the cavity of the larynx. It is hyaline cartilage and consists of two parts: a **quadrate** portion, situated behind, and a narrow ring or **arch**, one-fourth or one-fifth the depth of the posterior part, situated in front. The posterior square portion rapidly narrows at the sides of the cartilage, at the expense of the upper border, into the anterior portion.

Its **Posterior Portion** or **Lamina** (*lamina cartilaginis cricoideae*) is very deep and broad, and measures from above downward about an inch (2 to 3 cm.); it presents, on its posterior surface, in the middle line, a vertical ridge for the attachment of the longitudinal fibres of the oesophagus; and on either side a broad depression for the Crico-arytenoideus posticus muscle.

Its **Anterior Portion** or **Arcus** (*arcus cartilaginis cricoideae*) is narrow and convex, and measures vertically about one-fourth or one-fifth of an inch (5 to 7 cm.); it affords attachment externally in front and at the sides to the Crico-thyroid muscles, and, behind, to part of the Inferior constrictor.

At the point of junction of the posterior quadrate portion with the rest of the cartilage is a small round elevation, for articulation with the inferior cornu of the thyroid cartilage.

The **Lower Border** of the cricoid cartilage is horizontal, and connected to the upper ring of the trachea by fibrous membrane (Figs. 968 and 970).

Its **Upper Border** is directed obliquely upward and backward, owing to the great depth of the posterior surface. It gives attachment, in front, to the middle portion of the crico-thyroid membrane; at the sides, to the lateral portion of the same membrane and to the lateral Crico-arytenoid muscle; behind, it presents, in the middle, a shallow notch, and on each side of this is a smooth, oval surface, directed upward and outward, for articulation with the arytenoid cartilage.

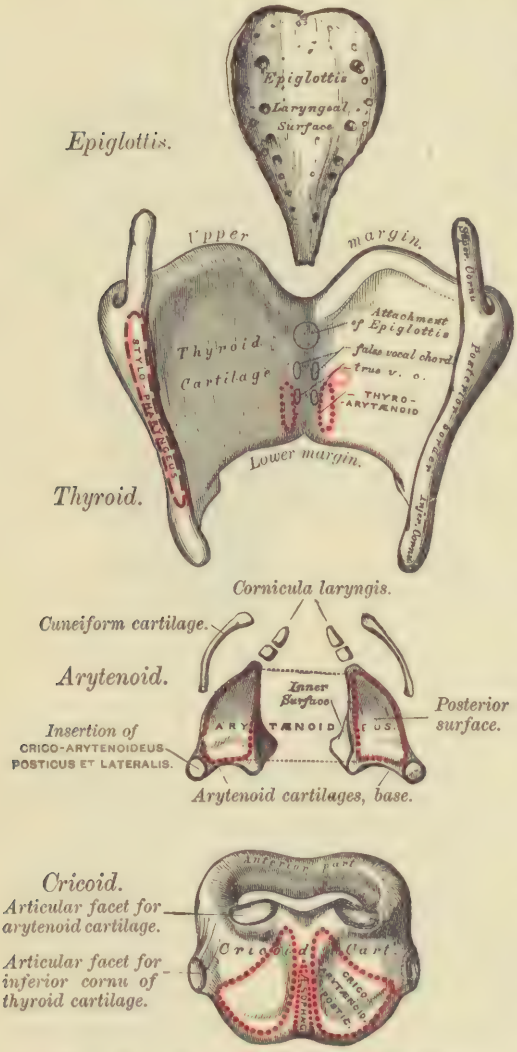

FIG. 969.—The cartilages of the larynx. Posterior view.

The **Inner Surface** of the cricoid cartilage is smooth, and lined with mucous membrane.

The Arytenoid Cartilages (*cartilagines arytaenoideae*) (Figs. 969, 972, and 976).—The arytenoid cartilages are so called from the resemblance they bear, when approximated, to the mouth of a pitcher (*ἀρύταινα, a pitcher*). They are two in number, and situated at the upper border of the cricoid cartilage, at the back of the larynx in the interval between the posterior borders of the alae of the thyroid cartilages. Each cartilage is in form a three-sided pyramid, and presents for examination **three surfaces**, a **base**, and an **apex**.

The **Posterior Surface** is triangular, smooth, concave, and gives attachment to the transverse portion of the Arytenoid muscle.

The **Anterior** or **External Surface** is somewhat convex and rough. It presents, near its apex, a small elevation, the **colliculus**; from this a **ridge** (*crista arcuata*) passes backward and then forward and downward into a sharp-pointed process, the **vocal process**. This ridge separates a deep depression above, the **fovea triangularis**, from a broader and shallower depression below, the **fovea oblonga**. A short distance above the base a small tubercle gives origin to the ligament of the false vocal cord, the superior thyro-arytenoid ligament. To the outer part of the ridge, as well as the surface above and below, is attached the Thyro-arytenoid muscle.

The **Internal Surface** is narrow, smooth, and flattened, covered by mucous membrane, and forms the lateral boundary of the respiratory part of the glottis.

The **Base** (*basis*) of each cartilage is broad, and presents a concave smooth surface, for articulation with the cricoid cartilage. Two of its angles require special mention: the **external angle**, which is short, rounded, and prominent, projects backward and outward, and is termed the **muscular process** (*processus muscularis*), from receiving the insertion of the Posterior and Lateral crico-arytenoid muscles. The **anterior angle**, also prominent, but more pointed, projects horizontally forward, and gives attachment to the inferior thyro-arytenoid ligament, the supporting ligament of the true vocal cord. This angle is called the **vocal process** (*processus vocalis*).

The **Apex** of each cartilage is pointed, curved backward and inward, and surmounted by a small conical, cartilaginous-nodule, the **corniculum laryngis**, articulated with or united to the arytenoid cartilage.

The Cornicula Laryngis or Cartilages of Santorini (*cartilagines corniculatae*) (Figs. 969 and 975).—The cornicula laryngis are two small conical nodules, consisting of white fibro-cartilage, which articulate with the summit of the arytenoid cartilages and serve to prolong them backward and inward. To them are attached the aryteno-epiglottidean folds. They are sometimes united to the arytenoid cartilages.

The Cuneiform Cartilages or Cartilages of Wrisberg (*cartilagines cuneiformes*) (Figs. 969 and 971).—The cuneiform cartilages are two small, elongated, cartilaginous bodies, placed one on each side, in the fold of mucous membrane which extends from the apex of the arytenoid cartilage to the side of the epiglottis, and is called the aryteno-epiglottidean fold (*plica aryepiglottica*) (Fig. 971); they give rise to small whitish elevations on the inner surface of the mucous membrane, just in front of the arytenoid cartilages.

The Epiglottis or the Cartilage of the Epiglottis (*cartilago epiglottica*) (Figs. 967, 969, 970, 971, 972, and 975).—The epiglottis is a thin, flexible lamella of fibro-cartilage, of a yellowish color, shaped like a leaf, and placed behind the tongue in front of the superior opening of the larynx. Its free extremity, which is directed upward, is broad and rounded, and often notched; its attached part (*petiolus epiglottidis*) is long, narrow, and connected to the receding angle between the alae of the thyroid cartilage, just below the median notch, by a long, narrow ligamentous band, the **thyro-epiglottic ligament** (*ligamentum thyreoepiglotticum*) (Fig. 972). It is also connected to the posterior surface of the body of the hyoid bone by an elastic ligamentous band, the **hyo-epiglottic ligament** (*ligamentum hyoepiglotticum*).

Its **Anterior** or **Lingual Surface** is curved forward, toward the tongue, and covered at its upper, free part by mucous membrane, which is reflected on to the sides and base of the organ, forming a median and two lateral folds, the **glosso-epiglottidean folds** (*plicae glossoepiglotticae*) (Fig. 971). The **median glosso-epiglottidean fold** (*plica glossoepiglottica mediana*) contains the elastic **glosso-epiglottic ligament** (*ligamentum glossoepiglotticum*). Each **lateral glosso-epiglottidean fold** (*plica glossoepiglottica lateralis*) runs from the front and side of the base of the epiglottis to the side of the tongue. The depression between the epiglottis and the base of the tongue on each side of the median fold is named the **vallecula epiglottica**. The lower part of the anterior surface of the epiglottis lies behind the hyoid bone, the thyro-hyoid membrane, and upper part of the thyroid cartilage, but is separated from these structures by a mass of fatty tissue.

Its **Posterior** or **Laryngeal Surface** is smooth, concave from side to side, concavo-convex from above downward; its lower part projects backward as an elevation, the **tubercle** or **cushion** (*tuberculum epiglotticum*) (Fig. 970); when the mucous membrane is removed, the surface of the cartilage is seen to be studded with a number of small mucous glands, which are lodged in little pits upon its surface. To its sides the **aryteno-epiglottidean folds** (*plicae aryepiglotticae*) are attached (Fig. 971).

Structure.—The cuneiform cartilages, the epiglottis, and the apices of the arytenoids are composed of yellow elastic cartilage, which shows little tendency to calcification; on the other hand, the thyroid, cricoid, and the greater part of the

arytenoids consist of hyaline cartilage, and become more or less ossified as age advances. Ossification commences about the twenty-fifth year in the thyroid cartilage, somewhat later in the cricoid and arytenoids; by the sixty-fifth year these cartilages may be completely converted into bone. The cornicula laryngis consist of white fibro-cartilage, which becomes osseous about the seventieth year.

Ligaments, Joints, and Membranes of the Larynx.—The ligaments of the larynx are *extrinsic*—*i. e.*, those connecting the thyroid cartilage and epiglottis with the hyoid bone, and the cricoid cartilage with the trachea; and *intrinsic*, those which connect the several cartilages of the larynx to each other.

The ligaments connecting the thyroid cartilage with the hyoid bone are three in number—the thyro-hyoid membrane, and the two lateral thyro-hyoid ligaments.

The **Thyro-hyoid** or **Hyo-thyroid Membrane** or **Ligament** (*membrana hyothyreoidea*) (Fig. 972) is a broad, fibro-elastic, membranous layer, attached below to the upper border of the thyroid cartilage, and above to the posterior border of the body and greater cornua of the hyoid bone, passing behind the postero-inferior surface of the hyoid, and being separated from this surface by a synovial bursa (*bursa m. sternohyoidei*), which facilitates the upward movement of the larynx during deglutition. The membrane is thicker in the middle line than at either side. This thickening is due to elastic fibres, and constitutes the **middle thyro-hyoid ligament** (*ligamentum hyothyreoideum medium*). On each side the posterior extremity of the membrane is thickened by elastic fibres, constituting the **lateral thyro-hyoid ligament** (*ligamentum hyothyreoideum laterale*). The thyro-hyoid membrane is pierced on each side by the **superior laryngeal vessels** and the **internal laryngeal nerve**. The anterior surface of the thyro-hyoid membrane is in relation with the Thyro-hyoid, Sterno-hyoid, and Omo-hyoid muscles and with the body of the hyoid bone. The two lateral ligaments are rounded, elastic cords, which pass between the superior cornua of the thyroid cartilage and the extremities of the greater cornua of the hyoid bone. A small cartilaginous nodule (*cartilago triticea*), sometimes bony, is frequently found in each.

The Membrana Quadrangularis is an elastic membrane containing numerous glands. The fibres of the membrane run in part downward and in part downward and backward. The membrane on each side arises in front and above at the lateral margin of the cartilage of the epiglottis, below at the posterior surface of the angle of the thyroid cartilage and becomes attached behind to the cornicula laryngis and to the inner margins of the arytenoid cartilages.[1] The membranes converge below and medianward. The **ligamentum ventriculare** is the superior end of the membrane (Spalteholz). The fibres constituting the ligamentum ventriculare are given off at the thyroid cartilage above the ligamentum vocale and pass horizontally backward to the medial margin of the fovea triangularis of the arytenoid cartilage.[2] The epiglottis is connected to the tongue by the three glosso-epiglottidean folds of mucous membrane, which may also be considered as extrinsic ligaments of the epiglottis.

The **Glosso-epiglottidean Folds** or **Ligaments** (*plicae epiglotticae*) (Fig. 971) number three. The **middle glosso-epiglottidean fold** (*plica glossoepiglottica mediana*) passes from the middle of the anterior free surface of the epiglottis to the base of the tongue. It contains the **glosso-epiglottic ligament.** The **lateral glosso-epiglottidean** or the **pharyngo-epiglottidean fold** (*plica glossoepiglottica lateralis*) on each side passes from the side of the epiglottis to the side of the base of the tongue and to the pharyngeal wall. On each side between the median and lateral folds is a depression, the **vallecula epiglottica.**

The **Hyo-epiglottic Ligament** (*ligamentum hyoepiglotticum*) is an elastic band, which extends from the anterior surface of the epiglottis, near its apex, to the

[1] Hand Atlas of Human Anatomy. By Werner Spalteholz. Translated and edited by Lewellys F. Barker.
[2] Spalteholz's Hand Atlas of Human Anatomy. Translated and edited by Lewellys F. Barker.

upper border of the body of the hyoid bone. The epiglottis is attached to the thyroid cartilage, below and behind the superior thyroid notch, by the strong and elastic **thyro-epiglottic ligament** (*ligamentum thyreoepiglotticum*) (Fig. 972). Between the epiglottis, the hyo-epiglottic ligament and the thyro-hyoid membrane is a triangular space containing fat on each side of the median line.

The ligaments connecting the thyroid cartilage to the cricoid are also three in number—the **crico-thyroid membrane** and the **capsular ligaments.**

The **Crico-thyroid Membrane** (*conus elasticus*) (Figs. 968 and 975) is an elastic membrane which passes radially from the posterior surface of the angle of the thyroid cartilage to the upper margin of the arch of the cricoid cartilage and to the vocal processes of the arytenoid cartilages. It is composed mainly of yellow elastic tissue. It consists of three parts, a central triangular portion and two lateral portions. The central part (*ligamentum cricothyreoideum medium*) is thick and strong, narrow above and broadening out below. It connects together the contiguous margins of the thyroid and cricoid cartilages. It is convex, concealed on each side by the Crico-thyroid muscle, but subcutaneous in the middle line; it is crossed horizontally by a small anastomotic arterial arch, formed by the junction of the two **crico-thyroid arteries.** The lateral portions are thinner and lie close under the mucous membrane of the larynx. They extend from the superior border of the cricoid cartilage to the inferior margin of the true vocal cords with which they are continuous. On each side are the uppermost fibres from the inferior thyro-arytenoid ligament (*ligamentum vocale*).

The lateral portions are lined internally by mucous membrane, and are separated from the thyroid cartilage by the lateral Crico-arytenoid and Thyro-arytenoid muscles. This membrane and the muscles just mentioned reduce greatly the interior of the larynx. The crico-thyroid membrane with the membrana quadrangularis constitute the **membrana elastica laryngis.**

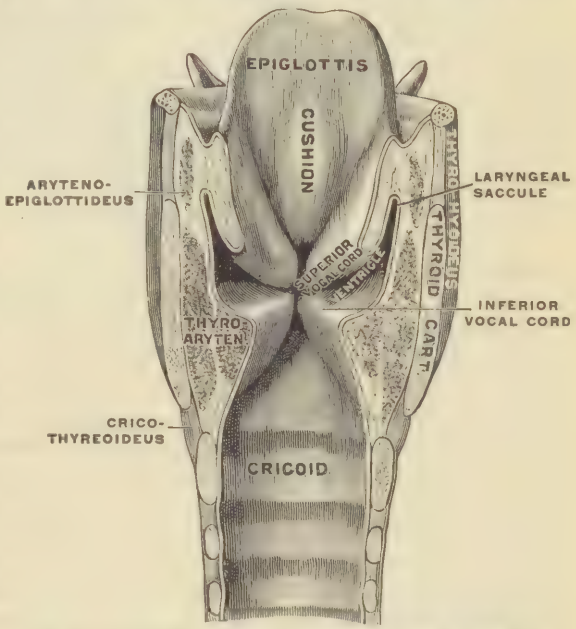

FIG. 970.—Coronal section of larynx, rear view of front half. (Testut.)

The **Crico-thyroid Articulation** (*articulatio cricothyreoidea*) (Fig. 968), on each side of the inferior cornu of the thyroid, with the cricoid cartilage on each side. A loose **synovial membrane** (*capsula articularis cricothyreoidea*) encloses the articulation.

The synovial capsule is strengthened by the ligamenta ceratocricoidea, which pass from the lesser cornu of the thyroid to the lamina of the cricoid cartilage.

The **Crico-arytenoid Articulation** (*articulatio cricoarytaenoidea*) (Fig. 969) on each side is between the articular surface of the arytenoid cartilage and the arytenoid articular surface of the cricoid cartilage.

The ligaments connecting the arytenoid cartilages to the cricoid are on each side a **capsular ligament** (*capsula articularis cricoarytaenoidea*) and a **posterior crico-arytenoid ligament** (*ligamentum cricoarytaenoideum posterius*). The capsular ligaments are thin and loose capsules attached to the margin of the articular

surfaces; they are lined internally by synovial membrane. The posterior crico-arytenoid ligaments extend from the cricoid to the inner and back part of the base of the arytenoid cartilage.

The **Crico-tracheal Ligament** (*ligamentum cricotracheale*) connects the cricoid cartilage with the first ring of the trachea. It resembles the fibrous membrane which connects the cartilaginous rings of the trachea to each side.

There is on each side an articulation between the arytenoid cartilage and the **cartilage of Santorini** (*synchondrosis arycorniculala*). The cartilage of Santorini is somewhat movable and is fixed to the arytenoid by lax connective tissue. From each cartilage of Santorini a band of connective tissue runs down to the lamina of the cricoid cartilage and to the pharyngeal mucous membrane. Beneath the arytenoid muscles the ligaments from the two sides join and pass down together. Thus is formed a Y-shaped ligament called the **ligamentum corniculopharyngeum.** The portion between the cricoid cartilage and the mucous membrane of the pharynx is sometimes called the **ligamentum cricopharyngeum.**

Interior of the Larynx (Figs. 970, 971, and 972).—The **cavity of the larynx** (*cavum laryngis*) extends from the superior aperture of the larynx to the lower border of the cricoid cartilage. It is divided into two parts by the projection inward of the true vocal cords, between which is a narrow triangular fissure or chink, the **rima glottidis.** It is further subdivided by the false vocal cords. So we consider the larynx as divided into a portion above the false cords, a portion between the false and true vocal cords, and a portion below the true cords. The entrance of the first compartment is the superior aperture of the larynx.

The Superior Aperture of the Larynx (*aditus laryngis*).—The superior aperture of the larynx (Figs. 970 and 971) is a triangular or cordiform opening, wide in front, narrow behind, and sloping obliquely downward and backward. It is bounded, in front, by the epiglottis; behind, by the apices of the arytenoid cartilages and the cornicula laryngis; and laterally, by a fold of mucous membrane, enclosing ligamentous and muscular fibres, stretched between the sides of the epiglottis and the apices of the arytenoid cartilages; these are the **aryteno-epiglottidean folds** (Figs. 971 and 972), on the margins of which the cuneiform cartilages form more or less distinct whitish prominences.

The small gap between the cartilages of Santorini is called the **incisura inter-arytaenoidea.** On the pharynx, on either side of the posterior portion of the superior aperture of the larynx, is a recess, called the **sinus pyriformis.**

Upper Compartment or Vestibule of the Laryngeal Cavity (*vestibulum laryngis*) (Figs. 970 and 972).—The vestibule is the portion between the superior opening and the false vocal cords. It is much narrower below than above. It is bounded anteriorly by the mucous membrane-covered epiglottis. The lower part of the epiglottis exhibits a prominence called the **cushion** or **tubercle** (*tuberculum epiglotticum*) (Fig. 970). The lateral wall of the vestibule on each side is the **aryteno-epiglottidean fold** (*plica aryepiglottica*) (Fig. 972), which extends from the summit of the arytenoid cartilage forward, upward, and outward to the margin of the epiglottis, and which contains fibres of the Thyro-epiglottideus and **Arytenoideus muscles** (*musculus arytaenoepiglottidean*). Near the posterior end of the fold are two trivial elevations: the anterior elevation is caused by the prominence of the cuneiform cartilage, and is called the **cuneiform tubercle of Wrisberg** (*tuberculum cuneiforme* [*Wrisbergi*]); the posterior elevation is caused by the anterior margin of the arytenoid cartilage and the cartilage of Santorini, and is called the **cornical tubercle of Santorini** (*tuberculum corniculatum* [*Santorini*]). Between these elevations is a groove, the **filtrum ventriculi of Merkel,** which passes into the space between the false and true vocal cords. The anterior elevation passes into the false vocal cord, the posterior elevation into the true vocal cord. The posterior portion of the laryngeal vestibule is the narrow space between the upper portions of the arytenoid cartilages.

The Middle Compartment of the Larynx (Figs. 970 and 972).—This lies between the false vocal cords above and the true vocal cords below. It is the smallest of the laryngeal compartments. It opens into the vestibule by the way of the gap between the false vocal cords, which is called the **false glottis**; it opens into the lower compartment of the larynx by way of the space between the true vocal cords, the **true glottis.**

The True Glottis.—The true glottis is the apparatus for producing tone and is formed by the true vocal cords.

The Chink of the Glottis (*rima glottidis*) (Figs. 970 and 971).—The chink of the glottis is the elongated fissure or chink between the inferior or true vocal cords in front, and between the bases and vocal processes of the arytenoid cartilages behind. It is therefore frequently subdivided into an anterior, interligamentous or **vocal portion**, the **glottis vocalis** (*pars intermembranacea*), and a posterior, intercartilaginous or **respiratory portion**, the **glottis respiratoria** (*pars intercartilaginea*). Posteriorly it is limited by the mucous membrane passing between the arytenoid cartilages. The vocal portion averages about three-fifths of the length of the entire aperture. It is the narrowest part of the cavity of the larynx, and its level corresponds to the

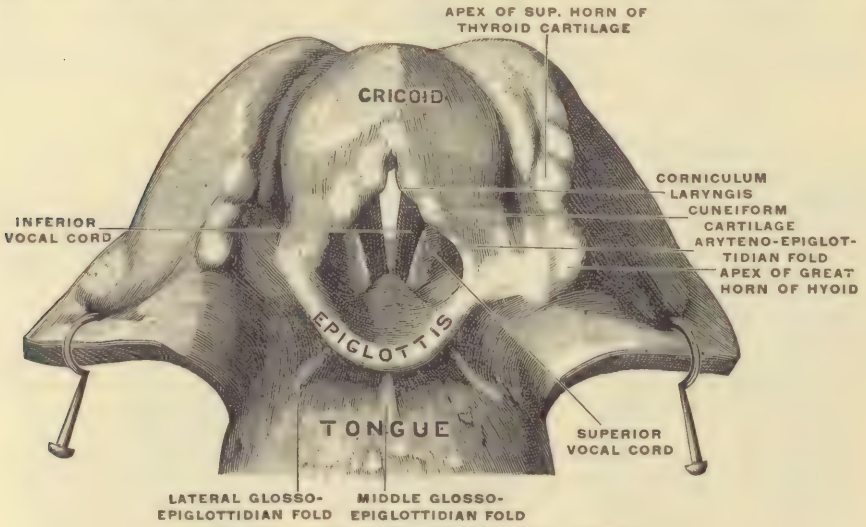

FIG. 971.—Larynx, viewed from above. (Testut.)

bases of the arytenoid cartilages. Its length, in the male, measures rather less than an inch (20 to 25 mm.); in the female it is shorter by 5 or 6 mm., or three lines. The width and shape of the rima glottidis vary with the movements of the vocal cords and arytenoid cartilages during respiration and phonation. In the condition of rest—*i. e.*, when these structures are uninfluenced by muscular action, as in quiet respiration, the glottis vocalis is triangular, with its apex in front and its base behind, the latter being represented by a line about 8 mm. long, connecting the anterior extremities of the vocal processes, while the inner surfaces of the arytenoids are parallel to each other, and hence the glottis respiratoria is rectangular. During extreme adduction of the cords, as in the emission of a high note, the glottis vocalis is reduced to a linear slit by the apposition of the cords, while the glottis respiratoria is triangular, its apex corresponding to the anterior extremities of the vocal processes of the arytenoids, which are approximated by the inward rotation of the cartilages. Conversely in extreme abduction of the cords, as in forced inspiration, the arytenoids and their vocal processes are rotated outward, and the glottis respiratoria is triangular in shape, but with its apex directed backward. In this condition the entire glottis is somewhat lozenge-shaped, the sides of the glottis vocalis diverging from before backward, those of the glottis

respiratoria diverging from behind forward, the widest part of the aperture corresponding with the attachment of the cords to the vocal processes.[1]

The **Superior** or **False Vocal Cords** (*plicae ventriculares*) (Figs. 970, 971, and 972), so called because they are not directly concerned in the production of the voice. Each is a thick fold of mucous membrane, enclosing a narrow band of fibrous tissue, the **superior thyro-arytenoid ligament** (*ligamentum ventriculare*), which is attached in front to the angle of the thyroid cartilage immediately below the attachment of the epiglottis, and behind to the anterior surface of the arytenoid cartilage. The lower border of this ligament, enclosed in mucous membrane, forms a free crescentic margin, which constitutes the upper boundary of the ventricle of the larynx. The false vocal cord contains the lower part of the membrana quadrangularis with the ligamentum ventriculare, the muscle ventricularis and laryngeal glands.

The **Inferior** or **True Vocal Cords** (*plicae vocales*) (Figs. 970, 971, 972, and 976), so called from their being concerned in the production of sound. Each is a strong

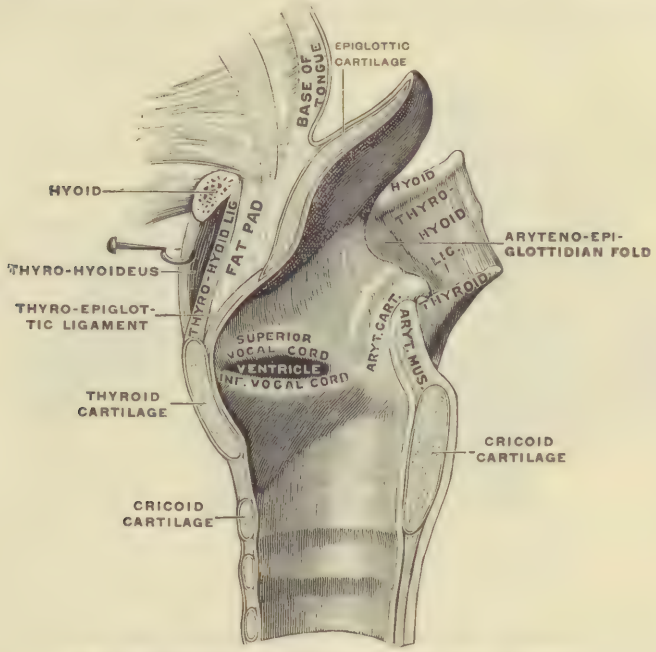

FIG. 972.—Sagittal section of larynx, right half. (Testut.)

band, the **inferior thyro-arytenoid ligament** (*ligamentum vocale*), covered on its surface by a thin layer of mucous membrane. Each ligament consists of a band of yellow elastic tissue, attached in front to the depression between the alae of the thyroid cartilage, and behind to the anterior angle of the base of the arytenoid. This angle is called the **vocal process**. Its lower border is continuous with the thin lateral part of the crico-thyroid membrane. Its upper border forms the lower boundary of the ventricle of the larynx. Externally, the Thyro-arytenoideus muscle lies parallel with it. It is covered internally by mucous membrane, which is extremely pale, thin, and closely adherent to its surface. The upper margin of the true vocal cord is covered with mucous membrane, and is the lower boundary of the ventricle of the larynx. Over the vocal process it is yellowish (*macula flava*). The true vocal cord contains the upper part of the crico-thyroid membrane with the ligamentum vocale and the muscle vocalis.

[1] On the shape of the rima glottidis, in the various conditions of breathing and speaking, see Czermak, On the Laryngoscope, translated for the New Sydenham Society.—ED. of 15th English edition.

The **Ventricle of the Larynx** or **Laryngeal Sinus** (*ventriculus laryngis* [*Morgagnii*]) (Figs. 970 and 972) is an oblong fossa, situated between the superior and inferior vocal cords on each side, and extending nearly their entire length. This fossa is bounded, above, by the free crescentic edge of the superior vocal cord; below, by the straight margin of the inferior vocal cord; externally, by the mucous membrane covering the corresponding Thyro-arytenoideus muscle. The anterior part of the ventricle leads up by a narrow opening into a caecal pouch of mucous membrane of variable size, called the **laryngeal pouch.**

The **Laryngeal Saccule** or **Pouch** (*appendix ventriculi*) (Fig. 970), or laryngeal pouch, is a membranous sac, placed between the superior vocal cord and the inner surface of the thyroid cartilage, occasionally extending as far as its upper border or even higher; it is conical in form, and curved slightly backward. On the surface of its mucous membrane are the openings of sixty or seventy mucous glands, which are lodged in the submucous areolar tissue. This sac is enclosed in a fibrous capsule, continuous below with the superior thyro-arytenoid ligament; its laryngeal surface is covered by the Aryteno-epiglottideus inferior muscle (*compressor sacculi laryngis of Hilton*); while its exterior is covered by the Thyro-arytenoideus and Thyro-epiglottideus muscles. These muscles compress the sacculus laryngis, and discharge the secretion it contains upon the vocal cords, the surfaces of which it is intended to lubricate.

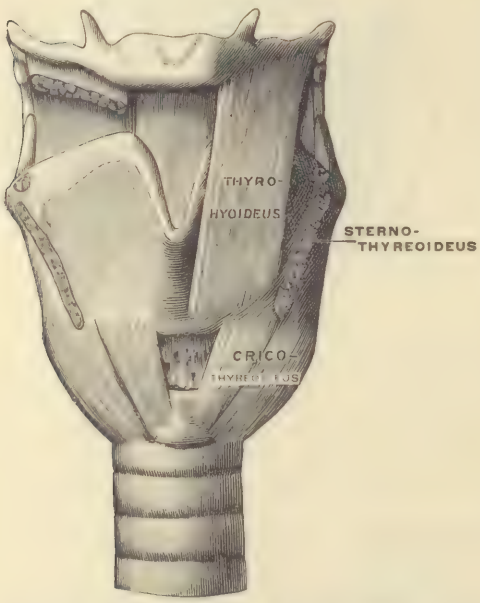

Fig. 973.—Muscles of larynx, front view. The sterno-thyroids and right thyro-hyoid have been removed. (Testut.)

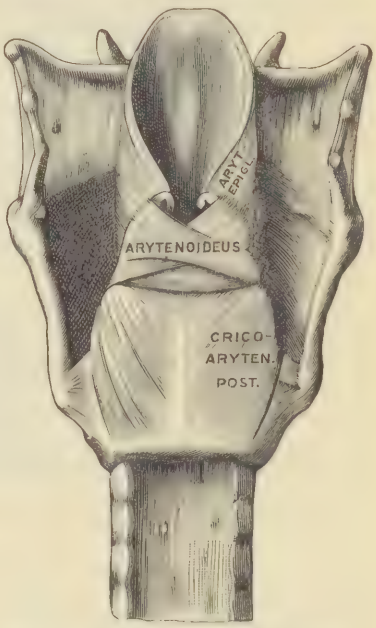

Fig. 974.—Muscles of larynx, from behind. (Testut.)

The Lower Compartment of the Larynx (Figs. 970 and 972).—This space is just beneath the true vocal cords and leads into the trachea. It is called the **additus glottidis inferior.** Above, on cross-section, it is oval; below, it is round. It is bounded by the inner surface of the crico-thyroid membrane and the cricoid cartilage.

Muscles of the Larynx (*musculi laryngis*).—We do not consider all muscles which are attached to laryngeal cartilages as laryngeal muscles. Some muscles so attached in reality belong to other regions, for instance, the Inferior constrictor, the Stylo-pharyngeus, the Sterno-thyroid, the Thyro-hyoid, and the Palato-pharyngeus. The muscles which really belong to the larynx are called *intrinsic.*

Four muscles of the vocal cords and rima glottidis are paired and one is single.

The paired muscles are the crico-thyroid, the posterior crico-arytenoid, the lateral crico-arytenoid, and the thyro-arytenoid. The single muscle is the arytenoideus.

A **Crico-thyroid** (*m. cricothyreoideus*) (Figs. 968, 970, and 973) is placed on each side. It is triangular in form, and situated at the forepart and side of the cricoid cartilage. It arises from the front and lateral part of the cricoid cartilage; its fibres diverge, passing obliquely upward and outward to be inserted into the lower border of the thyroid cartilage and into the anterior border of the lower cornu.

The inner borders of these two muscles are separated in the middle line by a triangular interval occupied by the central part of the crico-thyroid membrane.

The **Posterior Crico-arytenoid** (*m. cricoarytaenoideus posterior*) (Figs. 974, 975, and 976), a paired muscle, arises from the broad depression occupying each lateral half of the posterior surface of the cricoid cartilage; its fibres pass upward and outward, converging to be inserted into the outer angle (muscular process) of the base of the arytenoid cartilage. The upper fibres are nearly horizontal, the middle oblique, and the lower almost vertical.[1]

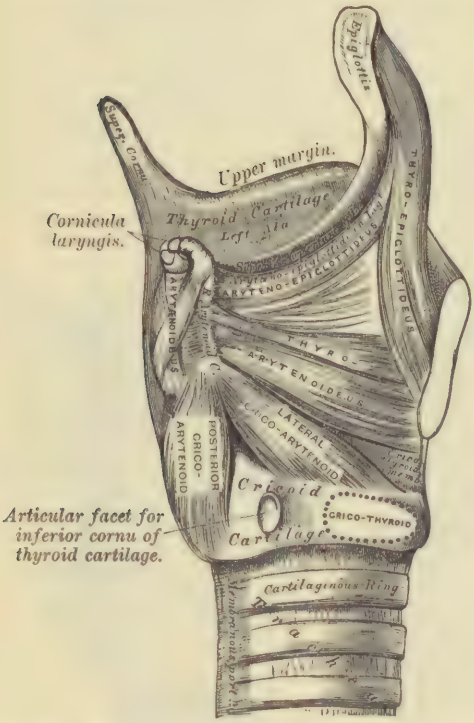

Fig. 975.—Muscles of larynx. Side view. Right ala of thyroid cartilage removed.

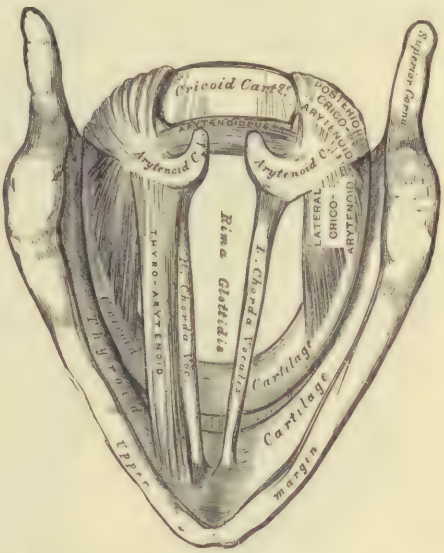

Fig. 976.—Interior of the larynx, seen from above. (Enlarged.)

The **Arytenoideus** (Figs. 972, 974, 975, and 976) is a single muscle filling up the posterior concave surface of the arytenoid cartilages. It arises from the posterior surface and outer border of one arytenoid cartilage, and is inserted into the corresponding parts of the opposite cartilage. It consists of three planes of fibres, two oblique and one transverse. The **oblique fibres** (*m. arytaenoideus obliquus*), the most superficial, form two fasciculi, which pass from the base of one cartilage to the apex of the opposite one. The **transverse fibres** (*m. arytaenoideus transversus*), the deepest and most numerous, pass transversely across between the two cartilages; hence the Arytenoideus was formerly considered as three muscles, the trans-

[1] Merkel, of Leipzig, has described a muscular slip which occasionally extends between the outer border of the posterior surface of the cricoid cartilage and the posterior margin of the inferior cornu of the thyroid; this he calls the "Musculus kerato-cricoideus." It is not found in every larynx, and when present exists usually only on one side, but is occasionally found on both sides. Sir William Turner (Edinburgh Medical Journal, February, 1860) states that it is found in about one case in five. Its action is to fix the lower horn of the thyroid cartilage backward and downward, opposing in some measure the part of the Crico-thyroid muscle, which is connected to the anterior margin of the horn.—Ed. of 15th English edition.

verse and the two oblique. A few of the oblique fibres are around the outer margin of the cartilage, and blend with the Thyro-arytenoid in the aryteno-epiglottidean fold, and are called the **Aryteno-epiglottideus** muscles.

In order to expose the rest of the muscles of the larynx the thyroid cartilage of one side must be removed. Begin by taking away the crico-thyroid muscle, then dividing the lateral thyro-hyoid ligament; disarticulate the inferior cornu of the thyroid cartilage from the cricoid cartilage, then carefully cut through the thyroid cartilage a short distance from its union with its twin. The following muscles will then be exposed after a little cleaning: the Lateral crico-thyroid, the Thyro-arytenoid, the Thyro-epiglottideus.

The **Lateral Crico-arytenoid** (*m. cricoarytenoideus lateralis*) (Figs. 975 and 976), a paired muscle, is smaller than the preceding, and of an oblong form. It arises from the upper border of the side of the cricoid cartilage, and, passing obliquely upward and backward, is inserted into the muscular process of the arytenoid cartilage in front of the posterior Crico-arytenoid muscle.

The **Thyro-arytenoid** (*m. thyroarytaenoideus*) (Figs. 975 and 976), a paired muscle, is broad and flat. It lies parallel with the outer side of the true vocal cord. It arises in front from the lower half of the receding angle of the thyroid cartilage, and from the crico-thyroid membrane. Its fibres pass backward and outward, to be inserted into the base and anterior surface of the arytenoid cartilage. This muscle consists of two fasciculi.[1] The **inner** or **inferior fasciculus** (*m. vocalis*), the thicker, is prismatic in shape and is inserted into the vocal process of the arytenoid cartilage, and into the adjacent portion of its anterior surface; it lies parallel with the true vocal cord, to which it is adherent. This fasciculus on its deeper surface gives off some fibres which are attached to the true vocal cord. These are called the ary-vocalis (Ludwig). The **outer** or **superior fasciculus**, the thinner, is inserted into the anterior surface and outer border of the arytenoid cartilage above the preceding fibres; it lies on the outer side of the sacculus laryngis, immediately beneath the mucous membrane.[2]

The muscles of the epiglottis are the—

Thyro-epiglottideus. Aryteno-epiglottideus superior.
Aryteno-epiglottideus inferior.

The **Thyro-epiglottideus** (*m. thyroepiglotticus*) is a delicate fasciculus, which arises from the inner surface of the thyroid cartilage, just external to the origin of the Thyro-arytenoid muscle, of which it is sometimes described as a part, and spreads over the outer surface of the sacculus laryngis; some of its fibres are lost in the aryteno-epiglottidean fold, while the others are continued forward to the margin of the epiglottis.

The **Aryteno-epiglottideus** (Figs. 970 and 975) is properly divided into two muscles, a superior and an inferior.

The **Aryteno-epiglottideus superior** consists of a few delicate muscular fasciculi, which arise from the apex of the arytenoid cartilages, and become lost in the fold of mucous membrane, the **aryteno-epiglottidean fold**, extending between the arytenoid cartilage and the side of the epiglottis.

The **Aryteno-epiglottideus inferior**, the **Compressor sacculi laryngis of Hilton**, arises from the arytenoid cartilage, just above the attachment of the superior vocal cord; passing forward and upward, it spreads out upon the anterior surface of the epiglottis. This muscle is separated from the preceding by an indistinct areolar interval.[3]

[1] Henle describes these two portions as separate muscles, under the names of the External and Internal thyro-arytenoid.—Ed. of 15th English edition.

[2] Luschka has described a small but fairly constant muscle as the Arytenoideus rectus. It is attached below to the posterior concave surface of the arytenoid cartilage, beneath the Arytenoideus muscle, and, passing upward, emerges at the upper border of this muscle, and is inserted into the posterior surface of the cartilage of Santorini (Anatomy, by Hyrtl, p. 718).—Ed. of 15th English edition.

[3] Musculus triticeo-glossus. Boehdalek, Jr. (Prager Vierteljahrsschrift, 1866, 2d part) describes a muscle hitherto entirely overlooked, except by Henle, who makes a brief statement in his Anatomy, which arises from the nodule of cartilage (*corpus triticeum*) in the posterior thyro-hyoid ligament, and passes forward and upward to enter the tongue along with the Hyo-glossus muscle. He met with this muscle eight times in twenty-two subjects. It occurred in both sexes, sometimes on both sides, at others on one only.—Ed. of 15th English edition.

Actions.—In considering the action of the muscles of the larynx, they may be conveniently divided into two groups, viz.: 1. Those which open and close the glottis. 2. Those which regulate the degree of tension of the vocal cords.

1. The muscles which open the glottis are the two Posterior crico-arytenoids; and those which close it are the Arytenoideus and the two Lateral crico-arytenoids. 2. The muscles which regulate the tension of the vocal cords are the two Crico-thyroids, which tense and elongate them, and the two Thyro-arytenoids, which relax and shorten them. The Thyro-epiglottideus is a depressor of the epiglottis, and the Aryteno-epiglottideus, superior and inferior, constrict the superior aperture of the larynx.

The *Posterior crico-arytenoids* separate the chordae vocales, and consequently open the glottis, by rotating the arytenoid cartilages outward around a vertical axis passing through the crico-arytenoid joints, so that their vocal processes and the vocal cords attached to them become widely separated.

The *Lateral crico-arytenoids* close the glottis by rotating the arytenoid cartilages inward so as to approximate their vocal processes.

The *Arytenoideus muscle* approximates the arytenoid cartilages, and thus closes the opening of the glottis, especially at its back part.

The *Crico-thyroid muscles* produce tension and elongation of the vocal cords. This is effected as follows: the thyroid cartilage is fixed by its extrinsic muscles; then the Crico-thyroid muscles, when they act, draw upward the front of the cricoid cartilage, and so depress the posterior portion, which carries with it the arytenoid cartilages, and thus elongate the vocal cords.

The *Thyro-arytenoid muscles*, consisting of two parts having different attachments and different directions, are rather complicated as regards their action. Their main use is to draw the arytenoid cartilages forward toward the thyroid, and thus shorten and relax the vocal cords. But, owing to the connection of the inner portion with the vocal cord, this part, if acting separately, is supposed to modify its elasticity and tension, and the outer portion, being inserted into the outer part of the anterior surface of the arytenoid cartilage, may rotate it inward, and thus narrow the rima glottidis by bringing the two cords together.

The *Thyro-epiglottidei* may depress the epiglottis; they assist in compressing the sacculi laryngis. The Aryteno-epiglottideus superior constricts the superior aperture of the larynx, when it is drawn upward, during deglutition. The *aryteno-epiglottideus inferior*, together with some fibres of the Thyro-arytenoidei, compress the sacculus laryngis.

The **Mucous Membrane of the Larynx** is continuous above with that lining the mouth and pharynx, and it is prolonged through the trachea and bronchi into the lungs. It lines the posterior surface and the anterior part of the upper surface of the epiglottis, to which it is closely adherent. In the rest of the larynx, above the true vocal cords, it is lax and rests upon a considerable submucous layer. The mucous membrane, with the submucous coat, ligamentous and muscular fibres, forms the aryteno-epiglottidean folds, which folds are the lateral boundaries of the superior aperture of the larynx. It lines the whole of the cavity of the larynx; forms by its reduplication the chief part of the superior or false vocal cord; and, from the ventricle, is continued into the sacculus laryngis. It is then reflected over the true vocal cords, where it is thin and very intimately adherent; covers the inner surface of the crico-thyroid membrane and cricoid cartilage; and is ultimately continuous with the lining membrane of the trachea. The forepart of the anterior surface and the upper half of the posterior surface of the epiglottis, the upper part of the aryteno-epiglottidean folds, and the true vocal cords are covered by stratified squamous epithelium; the rest of the laryngeal mucous membrane is covered by columnar ciliated cells.

The mucous membrane above the rima glottidis is extremely sensitive, and during life the lightest touch of a foreign body produces cough.

Glands.—The mucous membrane of the larynx is furnished with numerous muciparous glands, the orifices of which are found in nearly every part; they are very numerous upon the epiglottis, being lodged in little pits in its substance; they are also found in large numbers along the posterior margin of the aryteno-epiglottidean fold, in front of the arytenoid cartilages, where they are termed the

arytenoid glands. They exist also in large numbers upon the inner surface of the sacculus laryngis. None are found on the surface of the true vocal cords.

Vessels and Nerves.—The **arteries of the larynx** (Fig. 977) are the **laryngeal branches derived from the superior and inferior thyroid.** The **superior laryngeal artery from the superior thyroid** courses along by the internal laryngeal nerve; the **inferior laryngeal artery from the inferior thyroid** courses along with the recurrent laryngeal nerve. The **veins** accompany the arteries; those accompanying the superior laryngeal artery join the **superior thyroid vein** which opens into the internal jugular vein; while those accompanying the inferior laryngeal artery join the **inferior thyroid vein** which opens into the innominate vein. The laryngeal **lymphatics** arise from a network in the mucous membrane. This network is divisible into two portions, a superior and an inferior, which are to be regarded as almost independent areas. The superior region includes all of the "laryngeal mucous membrane above the glottis, epiglottis, aryteno-epiglottidean folds, interarytenoid region, and superior vocal cords."[1] The inferior area is the laryngeal mucous

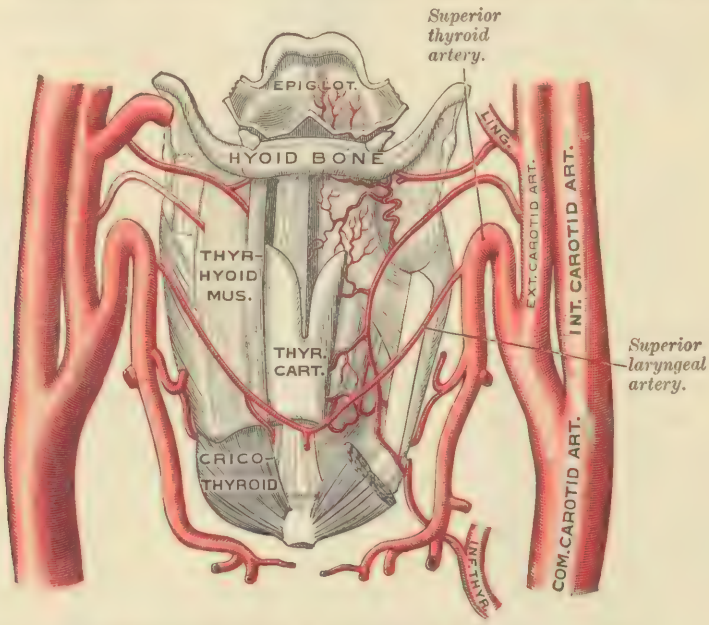

FIG. 977.—The origin and distribution of the arteries of the larynx. (Luschka.)

membrane below the glottis. The lymphatics of one-half of the larynx do not communicate with those of the other half in the median line in front, but do in the median line behind. The efferent vessels from the superior network accompany the superior laryngeal artery, pierce the thyro-hyoid membrane, and divide into three sets. One or two lymphatic vessels pass upward and terminate in a gland slightly below the posterior belly of the Digastric muscle. A group of vessels passes horizontally outward to terminate in the glands situated on the internal jugular vein on a level with the bifurcation of the common carotid artery. Another group descends and empties into the internal jugular group of glands at a lower level than the horizontal vessels. Trunks from the inferior network of the laryngeal mucous membrane form two groups. The anterior or supracricoid group consists of three trunks which pass through the crico-thyroid membrane, to empty into the pre-laryngeal glands, the pre-tracheal gland, and the middle and lower deep cervical glands.[2] The posterior group consists

[1] Philip R. W. De Santi in the Lancet, June 18, 1904.

[2] Poirier, Cunéo, Most, De Santi.

of "from three to five trunks, which pass over the crico-tracheal fascia at the junction of the lateral and posterior aspects of the trachea,"[1] and terminate in the recurrent glands about the recurrent laryngeal nerve. The **nerves** are derived from the **internal** and **external laryngeal branches of the superior laryngeal nerve,** from the **inferior** or **recurrent laryngeal,** and from the **sympathetic.** The internal laryngeal nerve is almost entirely sensory, but some motor filaments are said to be carried by it to the Arytenoideus muscle. It divides into a branch which is distributed to both surfaces of the epiglottis, a second to the aryteno-epiglottidean folds, and a third, the largest, which supplies the mucous membrane over the back of the larynx and communicates with the recurrent laryngeal. The external laryngeal nerve supplies the Crico-thyroid muscle. The recurrent laryngeal passes upward under the lower border of the Inferior constrictor, and enters the larynx between the cricoid and thyroid cartilages. It supplies all the muscles of the larynx except the Crico-thyroid and part of the Arytenoideus. The sensory branches of the laryngeal nerves form subepithelial plexuses, from which fibres ascend to end between the cells covering the mucous membrane.

Over the posterior surface of the epiglottis, in the aryteno-epiglottidean folds, and less regularly in some other parts, taste-buds, similar to those in the tongue, are found.

THE TRACHEA AND BRONCHI (Fig. 978).

The trachea or windpipe is a cartilaginous membranous, elastic, cylindrical tube, flattened posteriorly, which extends from the lower part of the larynx, on a level with the sixth cervical vertebra, to opposite the body of the fourth, or sometimes of the fifth, dorsal vertebra, where it divides (*bifurcatio tracheae*) into two **bronchi,** one for each lung. This point is at the level of the spine of the fourth dorsal vertebra. The trachea is found to be more deeply placed the lower down it is examined. It is in the median line, deviating below a very little to the right side. When a cross-section is made of the trachea it is seen that its anterior and lateral walls are rounded, but its posterior wall is flat (Fig. 982). The largest diameter of the tube is the middle; from this point the diameter diminishes toward the bronchi and toward the laryngeal end. The trachea measures about four inches and a half in length; its diameter from side to side is from three-quarters of an inch to an inch, being always greater in the male than in the female.

Relations.—The anterior surface of the trachea is convex, and covered **in the neck,** from above downward, by the isthmus of the thyroid gland, the inferior thyroid veins, the arteria thyroidea ima (when that vessel exists), the Sterno-hyoid and Sterno-thyroid muscles, the cervical fascia, and more superficially, by the anastomosing branches between the anterior jugular veins: **in the thorax** it is covered from before backward by the first piece of the sternum, the remains of the thymus gland, the left innominate vein, the arch of the aorta, the innominate and left common carotid arteries, and the deep cardiac plexus. Posteriorly, it is in relation with the oesophagus; laterally, **in the neck,** it is in relation with the common carotid arteries, the lateral lobes of the thyroid gland, the inferior thyroid arteries, and recurrent laryngeal nerves; and, **in the thorax,** it lies in the upper part of the **interpleural space,** that is, in the **superior mediastinum,** and is in relation on the right to the pleura and right vagus, and near the root of the neck to the innominate artery; on its left side are the recurrent laryngeal nerve, the aortic arch, the left common carotid and subclavian arteries.

The Right Bronchus (*bronchus dexter*).—The unbranched portion of the right bronchus, wider, shorter, and more vertical in direction than the left, is about an inch in length, and enters the hilum of the right lung opposite the fifth dorsal

[1] De Santi, in the Lancet, June 18, 1904.

vertebra. It forms an angle to the median plane of about 29 degrees. The vena azygos major arches over it from behind; and the right pulmonary artery lies below and then in front of it. About three-quarters of an inch from its commencement it gives off a branch to the upper lobe of the right lung. This is termed the **eparterial branch** (*ramus bronchialis eparterialis*), because it is given off above the right pulmonary artery. The bronchus now passes below the artery, and is

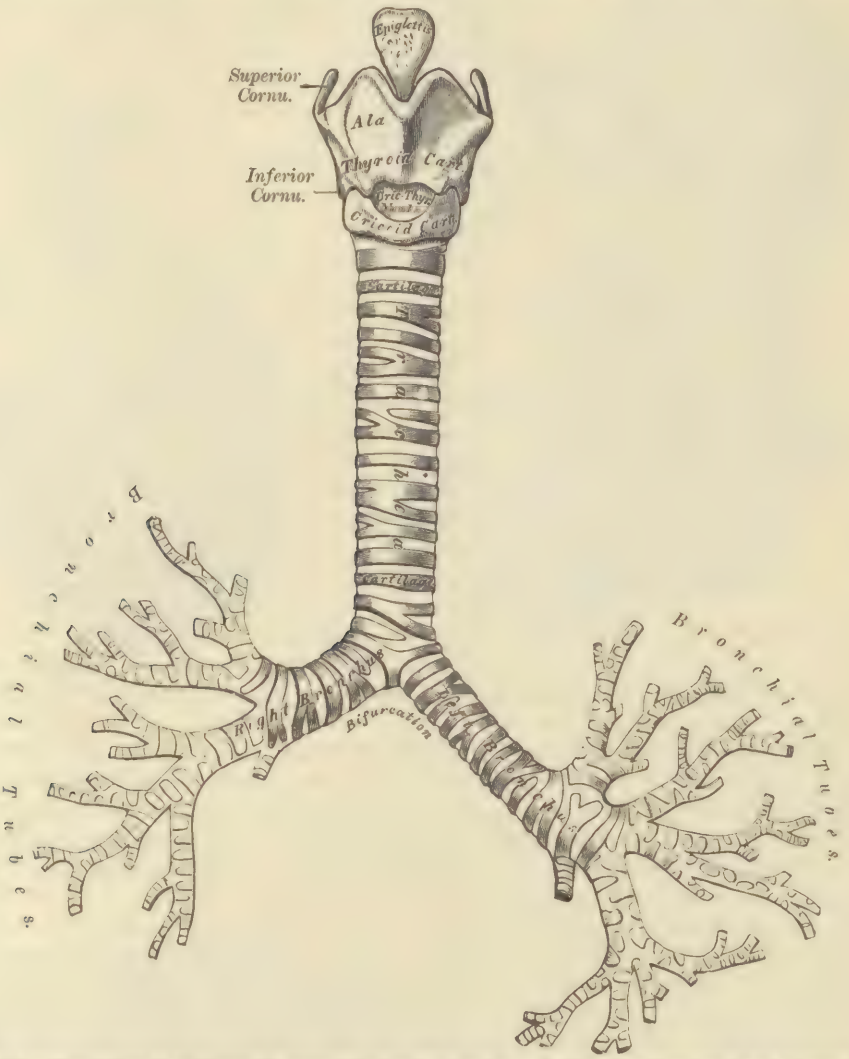

FIG. 978.—Front view of cartilages of larynx; the trachea and bronchi (the right bronchus is not shown as steep as it really is.

known as the **hyparterial branch** (*ramus branchialis hyparterialis*). It divides into two branches for the middle and lower lobs.

If a transverse section of the trachea is made a short distance above its point of bifurcation, and a bird's-eye view taken of its interior (Fig. 982), the septum placed at the bottom of the trachea and separating the two bronchi will be seen to occupy the left of the median line, and the right bronchus appears to be a more direct continuation than the left, so that any solid body dropping into the trachea would naturally be directed toward the right bronchus. This tendency is aided by the larger size of the right tube as compared with its fellow. This fact

serves to explain why a foreign body in the trachea more frequently falls into the right bronchus than into the left.[1]

The Left Bronchus (*bronchus sinister*).—The left bronchus is smaller and longer than the right, being nearly two inches in length. It forms an angle to the median plane of about 46 degrees. It is slightly curved and enters the root of the left lung, opposite the sixth dorsal vertebra, about an inch lower than the right bronchus. It passes beneath the arch of the aorta, crosses in front of the oesophagus, the thoracic duct, and the descending aorta, and has the left pulmonary artery lying at first above, and then in front of it. The left bronchus has no branch corresponding to the eparterial branch of the right bronchus, and therefore it has been supposed by some that there is no upper lobe to the left lung, but that the so-called upper lobe corresponds to the middle lobe of the right lung. The left bronchus does have an hyparterial branch.

FIG. 979.—Internal surface of the bronchi. (Poirier and Charpy.)

When the main or stem bronchus enters the lung on each side it appears to divide into nearly equal branches at the root of the lung, but a somewhat similar arrangement to what is found in many animals may be made out where each main bronchus passes downward and backward toward the extremity of the lower lobe, and ends near the posterior surface of the base of the lung, a portion of pulmonary substance which is between the Diaphragm and the wall of the chest. It gives off four branches, or **lateral bronchi** (*rami bronchiales*), at intervals in two directions, dorsally and ventrally, and, in addition, accessory branches, which arise from the front of the bronchus and pass mesially and dorsally into the inferior lobe. In the right bronchus the first ventral branch supplies the middle lobe, the other three and all the dorsal going to the lower lobe; in the left bronchus, the first ventral branch supplies the middle lobe, the other three and all the dorsal going to the lower lobe; in the left bronchus, the first central supplies the superior lobe, and all the others, both ventral and dorsal, go to the lower lobe. The dorsal and ventral branches divide into smaller branches, and these again into smaller branches or **bronchioles** (Fig. 981). Each bronchiolus divides into minute branches (*bronchioli respiratorii*) (Fig. 981), the walls of which show numerous areas of bulging called **alveoli** (Fig. 981). From the bronchioli respiratorii come the terminal branches of the bronchi. These terminal branches are the **alveolar ducts** (*ductuli alveolares*), and they are bulged by numerous alveoli (Fig. 981). They connect by openings at their termination with several cavities of irregular form, which are called **atria**. Each atrium is connected with several or many larger cavities, known as **sacculi alveolares, air-cells,** or **air-sacs** (*infundibula*). The entire surface of the air-sacs is filled with small cavities, the **pulmonary alveoli** (*alveoli pulmonis*). An alveolar duct with its branches forms a **pulmonary lobule** (*lobulus pulmonis*) (Fig. 980).

Structure of the Trachea.—The trachea is composed of imperfect cartilaginous rings, fibrous membrane, muscular fibres, mucous membrane, and glands.

The Cartilages.—The cartilages vary from sixteen to twenty in number; each forms an imperfect ring, which surrounds about two-thirds of the cylinder of the

[1] Reigel asserts that the entrance of a foreign body into the *left* bronchus is by no means so infrequent as is generally supposed. See also Med.-Chir. Transactions, vol. lxxi. p. 121.—ED. of 15th English edition.

trachea, being imperfect behind, where the tube is completed by fibrous membrane. The cartilages are placed horizontally above each other, separated by narrow membranous intervals. They measure about two lines in depth, and half a line in thickness. Their outer surfaces are flattened, but internally they are convex, from being thicker in the middle than at the margins. Two or more of the cartilages often unite, partially or completely, and are sometimes bifurcated at their extremities. They are highly elastic, but sometimes become calcified in advanced life. In the right bronchus the cartilages vary in number from six to eight; in the left, from nine to twelve. They are shorter and narrower than those of the trachea. The peculiar cartilages are the first and the last.

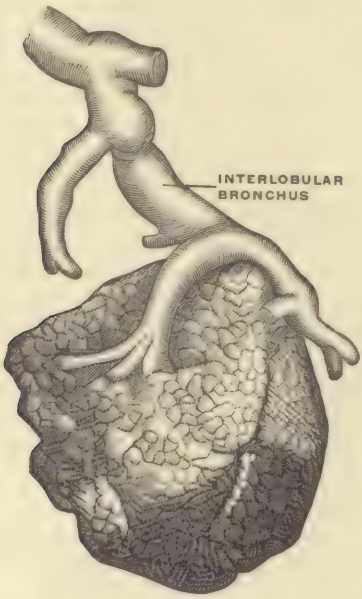

Fig. 980.—A pulmonary lobule. (Poirier and Charpy.)

The **First Cartilage** is broader than the rest, and sometimes divided at one end; it is connected by fibrous membrane with the lower

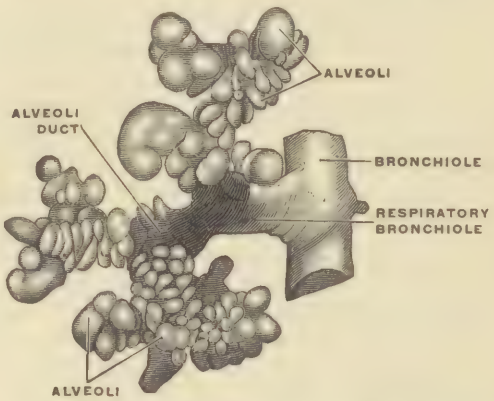

Fig. 981.—The terminal bronchial tubes. The respiratory bronchiole and alveoli. (Poirier and Charpy.)

border of the cricoid cartilage, with which or with the succeeding cartilage it is sometimes blended.

The **Last Cartilage** is thick and broad in the middle, in consequence of its lower border being prolonged into a triangular hook-shaped process which curves downward and backward between the two bronchi. It terminates on each side in an imperfect ring which encloses the commencement of the bronchi. The cartilage above the last is somewhat broader than the rest at its centre.

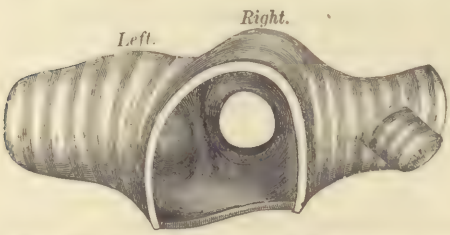

Fig. 982.—Transverse section of the trachea, just above its bifurcation, with a bird's-eye view of the interior.

The Fibrous Membrane.—The cartilages are enclosed in an elastic fibrous membrane which forms a double layer, one layer, the thicker of the two, passing over the outer surface of the ring, the other over the inner surface; at the upper and lower margins of the cartilages these two layers blend together to form a single membrane, which connects the rings one with another. They are thus, as it were, embedded in the membrane. In the space behind, between the extremities of the rings, the membrane forms a single distinct layer.

The Muscular Fibres.—The muscular fibres are disposed in two layers, **longitudinal** and **transverse**

The **Longitudinal Fibres** are the most external, and consist merely of a few scattered longitudinal bundles of fibres.

The **Transverse Fibres** constitute the **Trachealis muscle of Todd and Bowman.** The most internal form a thin layer which extends transversely between the ends of the cartilages and the intervals between them at the posterior part of the trachea. The muscular fibres are of the unstriped variety.

The Mucous Membrane.—The mucous membrane is continuous above with that of the larynx, and below with that of the bronchi. Microscopically, it consists of areolar and lymphoid tissue, and presents a well-marked basement-membrane, supporting a layer of columnar, ciliated epithelium, between the deeper ends of which are smaller triangular cells, the bases of which, often branched, are attached to the basement-membrane. These triangular cells are mucus-secreting, and may be seen as goblet-cells or chalice-cells when their contents have been discharged. In the deepest part of the mucous membrane, and especially between the mucous and submucous layers, longitudinally arranged fibres are very abundant and form a distinct layer.

The Tracheal Glands (*glandulae tracheales*).—The tracheal glands are found in great abundance at the posterior part of the trachea. They are racemose glands, and consist of a basement-membrane lined by columnar mucus-secreting cells. They are situated at the back of the trachea, outside the layer of muscular tissue, between it and the outer fibrous layer. Their excretory ducts pierce the muscular and inner fibrous layers, and pass through the submucous and mucous layers to open on the surface of the mucous membrane. Some glands of smaller size are also found at the sides of the trachea, between the layers of fibrous tissue connecting the rings, and others immediately beneath the mucous coat. The secretion from these glands serves to lubricate the inner surface of the trachea.

Vessels and Nerves.—The trachea is supplied with blood by the inferior thyroid arteries. The **veins** terminate in the thyroid venous plexus. The **nerves** are derived from the pneumogastric and its recurrent branches and from the sympathetic.

Lymphatic Glands.—The trachea is surrounded by lax connective tissue which contains numerous lymph glands, known as the **peritracheo-bronchial glands.** They are divided into four groups (Baréty). A group to the **right side,** in the angle between the trachea and right bronchus and ascending to the region of the subclavian vessels. A group to the **left side,** in the angle formed by the trachea and left bronchus, and ascending to about the arch of the aorta and the recurrent laryngeal nerve. The two groups just described are usually called **tracheal glands** (*lymphoglandulae tracheales*). A third group is in the angle formed by the bifurcation of the trachea. These constitute the **bronchial glands** (*lymphoglandulae bronchiales*). They number ten or twelve (Cunéo). A fourth group, the **interbronchial glands,** are found in angles of bifurcation of the larger bronchi in the lung parenchyma. Very early in life the peritracheo-bronchial glands become dark or even black from the deposition of carbonaceous substance brought by the leukocytes from the bronchial tubes. This condition is called **anthracosis.**

Surface Form. –In the middle line of the neck some of the cartilages of the larynx can readily be distinguished. In the receding angle below the chin the hyoid bone can easily be made out, and a finger's breadth below it is the pomum Adami, the prominence between the upper borders of the two alae of the thyroid cartilage. About an inch below this, in the middle line, is a depression corresponding to the crico-thyroid space, in which the operation of laryngotomy is performed. This depression is bounded below by a prominent arch, the anterior ring of the cricoid cartilage, below which the trachea can be felt, though it is only in the emaciated adult that the separate rings can be distinguished. The lower part of the trachea is not easily made out, for as it descends in the neck it takes a deeper position, and is farther removed from the surface. The level of the vocal cords corresponds to the middle of the anterior margin of the thyroid cartilage.

With the *laryngoscope*, the following structures can be seen: The base of the tongue and the upper surface of the epiglottis, with the glosso-epiglottic ligaments; the superior aperture of the larynx, bounded on either side by the aryteno-epiglottidean folds, in which may be seen two rounded eminences corresponding to the cornicula and cuneiform cartilages. Beneath these, the true and false vocal cords, with the ventricle between them. Still deeper, the cricoid cartilage and some of the anterior parts of the rings of the trachea, and sometimes, in deep inspiration, the bifurcation of the trachea.

Surgical Anatomy. *Foreign bodies* often find their way into the air-passages. These may be either large soft substances, as a piece of meat, which may become lodged in the upper aperture of the larynx or in the rima glottidis, and cause speedy suffocation unless rapidly got rid of, or unless an opening is made into the air-passages below, so as to enable the patient to breathe. Smaller bodies, frequently of a hard nature, such as cherry- or plum-stones, small pieces of bone, buttons, etc., may find their way through the rima glottidis into the trachea or bronchus, or may become lodged in the ventricle of the larynx. The dangers then depend not so much upon the mechanical obstruction as upon the spasm of the glottis which they excite from reflex irritation. When lodged in the ventricle of the larynx, they may produce very few symptoms beyond sudden loss of voice or alteration in the voice sounds, immediately following the inhalation of the foreign body. When, however, they are situated in the trachea, they are constantly striking against the vocal cords during expiratory efforts, and produce attacks of dyspnœa from spasm of the glottis. When lodged in the bronchus, they usually become fixed there, and, occluding the lumen of the tube, cause a loss of the respiratory murmur on the affected side, which is, as stated above, more often the right.

Beneath the mucous membrane of the upper part of the air-passages there is a considerable amount of submucous tissue which is liable to become much swollen from effusion in inflammatory affections, constituting the disease known as "*œdema of the glottis*." This effusion does not extend below the level of the true vocal cords, on account of the fact that the mucous membrane is closely adherent to these structures, without the intervention of any submucous tissue. So that, in cases of this disease in which it is necessary to open the air-passages to prevent suffocation, the operation of laryngotomy is sufficient.

Chronic laryngitis is an inflammation of the mucous glands of the larynx, which occurs in those who speak much in public, and is known as "*clergyman's sore throat*." It is due to the dryness induced by the large amount of cold air drawn into the air-passages during prolonged speaking, which incites increased activity in the mucous glands to keep the parts moist, and this eventually terminates in inflammation of these structures.

Ulceration of the larynx may occur from syphilis, either as a superficial ulceration, or from the softening of a gumma; from tuberculous disease (laryngeal phthisis), or from malignant disease (epithelioma).

The air-passages may be opened surgically in two different situations: through the crico-thyroid membrane (*laryngotomy*), or in some part of the trachea (*tracheotomy*); and to these some surgeons have added a third method, by opening the crico-thyroid membrane and dividing the cartilage with the upper ring of the trachea (*laryngo-tracheotomy*).

Laryngotomy is anatomically the more simple operation: it can readily be performed, and should be employed in those cases where the air-passages require opening in an emergency for the relief of some sudden obstruction to respiration. The crico-thyroid membrane is very superficial, being covered only in the middle line by the skin, superficial fascia, and the deep fascia. On each side of the middle line it is also covered by the Sterno-hyoid and Sterno-thyroid muscles, which diverge from each other at their upper parts, leaving a slight interval between them. On these muscles rest the anterior jugular veins. The only vessel of any importance in connection with this operation is the crico-thyroid artery, which crosses the crico-thyroid membrane, and which may be wounded, but rarely gives rise to any trouble. The operation is performed thus: the head being thrown back and steadied by an assistant, the finger is passed over the front of the neck, and the crico-thyroid depression felt for. A vertical incision is then made through the skin, in the middle line over this spot, and carried down through the fascia until the crico-thyroid membrane is exposed. A cross-cut is then made through the membrane, close to the upper border of the cricoid cartilage, so as to avoid, if possible, the crico-thyroid artery, and a tracheotomy tube is introduced. It has been recommended, as a more rapid way of performing the operation, to make a transverse instead of a longitudinal cut, through both the superficial and deep structures, and thus to open at once the air-passages. It will be seen, however, that in opening in this way the anterior jugular veins would be in danger of being wounded.

Tracheotomy may be performed either above or below the isthmus of the thyroid body, or this structure may be divided and the trachea opened behind it.

The isthmus of the thyroid gland usually crosses the second and third rings of the trachea; along its upper border is frequently to be found a large transverse communicating branch between the superior thyroid veins; and the isthmus itself is covered by a venous plexus formed between the thyroid veins of the opposite sides. Theoretically, therefore, it is advisable to avoid dividing this structure in opening the trachea.

Above the isthmus the trachea is comparatively superficial, being covered by the skin, superficial fascia, deep fascia, Sterno-hyoid and Sterno-thyroid muscles, and a second layer of the deep fascia, which, attached above to the lower border of the hyoid bone, descends beneath the muscles to the thyroid body, where it divides into two layers and encloses the isthmus.

Below the isthmus the trachea lies much more deeply, and is covered by the Sterno-hyoid and the Sterno-thyroid muscles and a quantity of loose areolar tissue in which is a plexus of veins, some of them of large size; they converge to two trunks, the inferior thyroid veins, which descend on either side of the median line on the front of the trachea and open into the innominate veins. In the infant the thymus gland ascends a variable distance along the front of the trachea, and opposite the episternal notch the windpipe is crossed by the left innominate vein. Occasionally, also, in young subjects, the innominate artery crosses the tube obliquely above the level of the sternum. The thyroidea ima artery, when that vessel exists, passes from below upward along the front of the trachea.

From these observations it must be evident that the trachea can be more readily opened above than below the isthmus of the thyroid body.

Tracheotomy above the isthmus is performed thus: the patient should, if possible, be laid on his back on a table in a good light. A pillow is to be placed under the shoulders and the head thrown back and steadied by an assistant. The surgeon standing on the right side of his patient makes an incision from an inch and a half to two inches in length in the median line of the neck from the top of the cricoid cartilage. The incision must be made exactly in the middle line, so as to avoid the anterior jugular veins, and after the superficial structures have been divided the interval between the Sterno-hyoid muscles must be found, the raphé divided, and the muscles drawn apart. The lower border of the cricoid cartilage must now be felt for, and the upper part of the trachea exposed from this point downward in the middle line. Bose has recommended that the layer of fascia in front of the trachea should be divided transversely at the level of the lower border of the cricoid cartilage, and, having been seized with a pair of forceps, pressed downward with the handle of the scalpel. By this means the isthmus of the thyroid gland is depressed, and is saved from all danger of being wounded, and the trachea is cleanly exposed. The trachea is now transfixed with a sharp hook and drawn forward in order to steady it, and is then opened by inserting the knife into it and dividing the two or three upper rings from below upward. If the trachea is to be opened below the isthmus, the incision to expose it must be made from a little below the cricoid cartilage to the top of the sternum.

In the child the trachea is smaller, more deeply placed, and more movable than in the adult. In fat or short-necked people, or in those in whom the muscles of the neck are prominently developed, the trachea is more deeply placed than in others.

A portion of the larynx or the whole of it has been removed for malignant disease, *laryngectomy*.

Some surgeons do preliminary tracheotomy, insert a Trendelenburg cannula to prevent the flow of blood downward into the lungs, and then remove the larynx. Other surgeons do not employ preliminary tracheotomy.

Perier's method of laryngectomy is as follows: Make a vertical incision in the median line from the level of the hyoid bone to below the level of the cricoid cartilage. Make a transverse incision at each end of the vertical incision. This makes an I-shaped wound.

Separate the soft parts from the larynx and upper part of the trachea, and separate these two structures from the œsophagus. After arresting bleeding, divide the trachea below the cricoid cartilage, introduce a special cannula, complete the removal of the larynx, suture the opening of the trachea to the lower angle of the wound, and close the rest of the wound after securing drainage. In malignant disease of the larynx the associated lymphatic glands must be removed.

Partial laryngectomy, according to Sir F. Semon, is the removal of not less than one wing of the thyroid cartilage. Removal of a lesser piece of the thyroid or of a bit of the arytenoid or cricoid he considers with the operation of thyrotomy.

THE PLEURAE (Figs. 983, 984, 985, 986, 987).

Each lung is invested, upon its external surface, by an exceedingly delicate serous membrane, the **pleura**, which encloses the organ as far as its root, and is then reflected upon the inner surface of the thorax. The portion of the serous membrane investing the surface of the lung and dipping into the fissures between its lobes is called the **pulmonary pleura** or the **visceral layer of the pleura** (*pleura pulmonalis*) (Fig. 983), while that which lines the inner surface of the chest is called the **parietal layer of the pleura** (*pleura parietalis*) (Fig. 983). The two layers join at the hilum of the lung. The space between these two layers is called the **cavity of the**

pleura (*cavum pleurae*), and contains a very little clear fluid. It must be borne in mind that in the healthy condition the two layers are in contact, and there

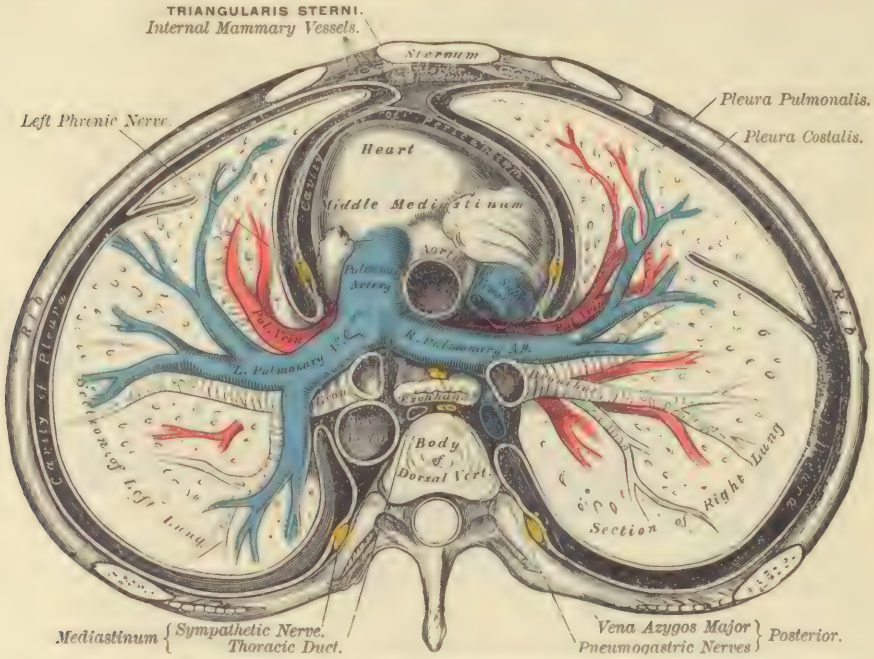

FIG. 983.—A transverse section of the thorax, showing the relative position of the viscera and the reflections of the pleurae.

is no real cavity until the lung becomes collapsed and separates from the wall of the chest. Each pleura is therefore a shut sac, one occupying the right, the other the left half of the thorax, and they are perfectly separate from each other.

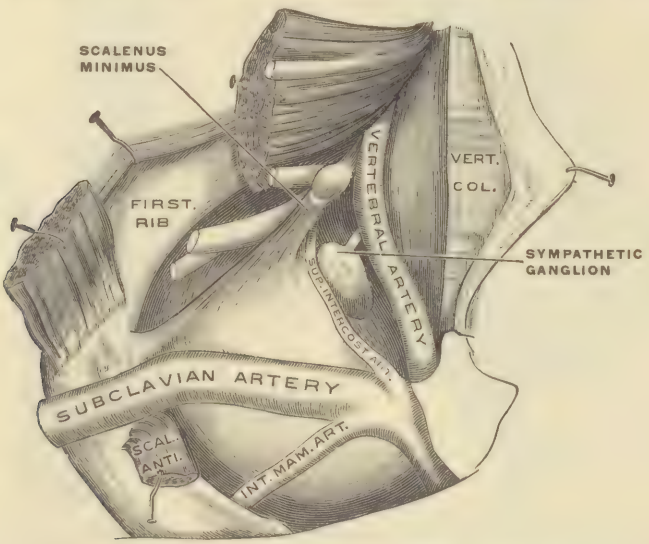

FIG. 984.—The dome of the pleura. (Poirier and Charpy.)

The two pleurae do not meet in the middle line of the chest, excepting anteriorly opposite the second and third pieces of the sternum—a space being left between

them, which contains all the viscera of the thorax excepting the lungs; this is the **mediastinum.**

Reflections of the Pleurae (Fig. 983). **The Pleura Pulmonalis** (Fig. 983). —The pleura pulmonalis is closely attached to the surface of the lung and enters into the

depths of the interlobar fissures. It leaves the lung surface at the hilum, covers the root of the lung for a little way (Figs. 990 and 991), and then passes into the medi-

astinal pleura. Between the hilum and the mediastinal pleura there is a thickened pleural fold, triangular in outline, and called the **ligamentum pulmonale** or the **ligamentum latum pulmonis** (Figs. 990 and 991). It is formed by the two layers of the pulmonary pleura coming in contact below the root of the lung. This fold passes from the lower part of the inner pulmonary surface to the pericardium, and the lower border is free or attached to the diaphragmatic pleura. In the right lung the origin of this ligament is in front of the groove for the azygos vein; in the left lung it is in front of the groove for the thoracic aorta.

The Pleura Parietalis.—The pleura parietalis is a continuous membrane, but for convenience is divided into the **cervical pleura, costal pleura, mediastinal pleura,** and **diaphragmatic pleura.**

The **Cervical Pleura** or **Dome of the Pleura** or **Cupola** (*cupula pleurae*) (Fig. 986) is the dome-shaped roof of the cavity of the pleura. It projects above the apex of the lung to the neck of the first rib. As the first rib is placed obliquely, the dome of the pleura reaches from one inch to two inches above the anterior extremity of the first rib, and from one-half an inch to one and one-half inches above the clavicle. On the outer side of the cervical pleura are the Scalenus anticus and medius muscles. Just below the apex, on the anterior and inner surface, is a groove for the subclavian artery, which vessel passes over it in an arch (Fig. 984). A little below the groove for the subclavian artery is a broader and shallower groove for the innominate and subclavian veins. Above the subclavian artery and in front and above the cervical pleura are the cords of origin of the brachial plexus and the inferior cervical ganglion (Fig. 984). The dome is strengthened and kept in place by **Sibson's aponeurosis** or the **vertebro-pleural ligament** (Figs. 985 and 986). This comes from a little piece of muscle, the **Scalenus minimus** muscle, which originates from the transverse process of the seventh cervical vertebra, broadens and becomes aponeurotic as it descends, and is inserted into the inner margin of the first rib (Figs. 984 and 985). It is also strengthened by the **costa-pleural ligament** (Fig. 985), from the inner surface of the neck of the first rib to the pleura, and by fibrous bands which pass to the tissue about the subclavian sheath, trachea, and oesophagus (Fig. 985).

The **Costal Pleura** (*pleura costalis*) (Fig. 983) is the shortest portion of the pleura and is connected to the parts it covers by the **endothoracic fascia** (*fascia endothoracica*), a layer of connective tissue which is much thicker back of the rib cartilages than it is posteriorly. The costal pleura covers the inner surface of part of the sternum, the costal cartilages, ribs, and Intercostal muscles, and the sides of the bodies of the dorsal vertebrae. This layer is loosely attached except as it passes from the heads of the ribs to the vertebrae, where it is firmly adherent.

The **Mediastinal Pleura** (*pleura mediastinalis*) (Fig. 985) covers the septum of the mediastinum, which intervenes between the two pleural cavities. The mediastinal pleura extends from the inner surface of the anterior wall of the thorax to the vertebrae. It is continuous in front and back with the costal pleura of the same side, the lines of junction being known, respectively, as the **anterior line of pleural reflection** and the **posterior line of pleural reflection.** Below the mediastinal pleura passes into the diaphragmatic pleura of the same side. The portion of the mediastinal pleura which fuses with the parietal layer of the pericardium is called the **pericardial pleura** (*pleura pericardiaca*).

Above the root of the lung the mediastinal pleura passes back directly to the vertebrae. "In this region the **left mediastinal pleura** is applied to the arch of the aorta and the phrenic and vagus nerves; to the left innominate vein, the left superior intercostal vein, and the left common carotid, and left subclavian arteries; to the oesophagus and the thoracic duct. The **right mediastinal pleura,** on the other hand, is applied, above the level of the root of the lung, to the upper part of the vena cava and right innominate vein; to the right innominate artery; to the vena azygos major, as it hooks forward above the bronchus; to the vagus and phrenic

nerves; and to the right side of the trachea."[1] Upon the pericardium the phrenic nerve is covered by the pleura. Back of the root of the lung and the pulmonary ligament, the right mediastinal pleura passes back to the vertebrae to the left of the oesophagus; the left mediastinal pleura passes back over the descending aorta, and just above the Diaphragm and in front of the aorta over the lower end of the oesophagus.

The **Diaphragmatic Pleura** (*pleura diaphragmatica*) (Figs. 987 and 988) covers the upper surface of the Diaphragm outside of the base of the pericardium, but does not completely cover it; for it does not pass into the interval between the wall of the thorax and Diaphragm, and before this point is reached becomes continuous with the costal pleura.

The reflection to the costal pleura begins by the sternum, at the lower margin of the sixth rib; takes place at the junction of the cartilage of the rib with the seventh rib; posteriorly, it takes place at the lower margin of the twelfth dorsal vertebra.

In the front of the chest, where the parietal layer of the pleura is reflected backward to the pericardium, the two pleural sacs are in contact for a considerable extent. At the upper part of the chest, behind the manubrium, they are not in contact; the point of reflection being represented by a line drawn from the sternoclavicular articulation to the mid-point of the junction of the manubrium to the body of the sternum. From this point the two pleurae descend in close contact to the level of the fourth costal cartilages Here the line of reflection on the right side is continued downward in nearly a straight line to the lower end of the gladiolus and then turns outward behind the costal cartilage of the sixth rib, continuing to descend and to run outward, it passes behind the descending part of the seventh costal cartilage, and meets the axillary line at the junction of the eighth rib with the cartilage. The line of reflection continues to descend till it reaches its lowest point at the tenth rib. This point is in the axillary line, while on the left side the line of reflection diverges outward, so that opposite the seventh cartilage it is about three-quarters of an inch from the left border of the sternum. It, however, always extends considerably farther over the pericardium than the corresponding lung. From this joint the reflections of the two sides are practically the same. The lower limit of the pleura is on a considerably lower level than the lower limit of the lung, but does not extend to the attachment of the Diaphragm, so that below the line of reflection of the pleura from the chest wall on to the Diaphragm the latter is in direct contact with the rib cartilages and the Internal intercostal muscles. In ordinary inspiration the thin margin of the base of the lung does not extend as low as the line of pleural reflection, with the result that the costal and diaphragmatic pleura are here in contact, the narrow slit between the two being termed the **phrenico-costal sinus** (*sinus phrenicocostalis*) (Fig. 987). A similar condition exists behind the sternum and rib cartilages, where the anterior thin margin of the lung falls short of the line of pleural reflection, and where the slit-like cavity between the two layers of pleura forms what is sometimes called the **costo-mediastinal sinus** (*sinus costomediastinalis*).

Along the line of reflection of the diaphragmatic pleura a dense fascia passes from the costal cartilages and the uncovered portion of the Diaphragm to the costal pleura. This serves to hold it in place. It is named by Cunningham the **phrenico-pleural fascia.**

The inner surface of the pleura is smooth, polished, and moistened by a serous fluid; its outer surface is intimately adherent to the surface of the lung, and to the pulmonary vessels as they emerge from the pericardium; it is also adherent to the upper surface of the Diaphragm; throughout the rest of its extent it is somewhat thicker, and may be separated from the adjacent parts with extreme facility.

[1] Cunningham's Text-book of Anatomy.

The right pleural sac is shorter, wider, and reaches higher in the neck than the left.

Structure of the Pleura.—The pleura is composed of connective tissue containing much elastic tissue, its free surface being covered with flat endothelial cells. It is fastened to adjacent structures by subserous areolar tissue. The subserous tissue of the visceral pleura is continuous with the areolar tissue of the lung.

Vessels and Nerves.—The **arteries of the pleura** are derived from the **intercostal**, the **internal mammary**, the **musculo-phrenic, thymic, pericardiac,** and **bronchial.** The **veins** correspond to the arteries. The **lymphatics** are very numerous in the pleura and subserous tissue. Many of them are in direct communication with the pleural cavity by **stomata** between the endothelial cells. Stomata are absent in the mediastinal pleura and over the ribs (Dyskowsky). The lymphatics of the visceral layer empty into the **superficial pulmonary trunks**; the lymphatics of the costal pleura empty into the **intercostal trunks**; of the diaphragmatic pleura, into the **diaphragmatic trunks**; of the mediastinal pleura, into the **posterior mediastinal glands.**[1] The **nerves** are derived from the **phrenic** and **sympathetic** (Luschka). Kölliker states that nerves accompany the ramification of the bronchial arteries in the pleural pulmonalis.

Surgical Anatomy.—In *operations upon the kidney* it must be borne in mind that the pleura may sometimes extend below the level of the last rib, and may therefore be opened in these operations, especially when the last rib is removed, in order to give more room. It is best to keep the incision at least one inch below the last rib, enlarging the wound afterward, when the finger can be introduced as a guide.

In *wounds of the Diaphragm* the pleura may be injured. In *operations about the root of the neck*, especially in the removal of glands and the ligation of the first part of the subclavian artery, the pleura may be injured.

Punctured wounds of the root of the neck are apt to reach the pleura.

Empyema is a surgical disease. In *acute empyema* the treatment is drainage. A portion of the fifth or sixth rib in the axillary line is removed by subperiosteal resection, the pleura is opened, and a tube is introduced. In *chronic empyema* the lung is contracted and adherent and cannot expand; hence drainage will not cure it. It is necessary to perform multiple rib resection in order to permit the chest-wall to sink in and obliterate the cavity, which, as the lung is unable to expand, it cannot do. The necessary operation may be the operation of Estlander, or the operation of Schede, or the operation of Fowler (page 166).

If a large wound admits suddenly a quantity of air into the pleura, dangerous or fatal *pneumothorax* arises, and the lung collapses. This is best met during operations by using the Fell-O'Dwyer apparatus for artificial respiration as advised by Matas.[2] This apparatus keeps the lung expanded, in spite of the entrance of air into the pleural sac. In *surgical pneumothorax* the lung may be sutured to the chest-wall, so as to block the opening. Sometimes, in order to arrest dangerous *pulmonary bleeding*, a surgeon deliberately induces pneumothorax, in hope that the collapse of the lung will arrest bleeding.

When an abscess of the liver is posterior and on the dorsum, *transpleural hepatotomy* is performed. A portion of the tenth and eleventh ribs below the angle of the scapula is removed. As a rule, the pleura is found obliterated at this point. If it is opened, it is at once sutured or closed with gauze packing. The exposed Diaphragm is incised, and, as it is usually adherent to the liver, the abscess cavity is entered. If it is not adherent, the liver is exposed and the abscess sought for with an aspirating-needle.

THE MEDIASTINAL SPACE, INTERPLEURAL SPACE OR MEDIASTINUM.

The mediastinum is the space left in the median portion of the chest by the non-approximation of the two pleuræ. It extends from the sternum in front to the spine behind. Within it are the contents of the thorax excepting the lungs. The mediastinum may be divided for purposes of description into two parts—an upper portion, above the upper level of the pericardium, which is named the

[1] Poirier, Cunéo, and Delamare on the Lymphatics. Translated and edited by Cecil H. Leaf.
[2] Annals of Surgery, April, 1899.

superior mediastinum (Struthers); and a lower portion, below the upper level of the pericardium. This lower portion is again subdivided into three—that part which contains the pericardium and its contents, the **middle mediastinum**; that part which is in front of the pericardium, the **anterior mediastinum**; and that part which is behind the pericardium, the **posterior mediastinum.**

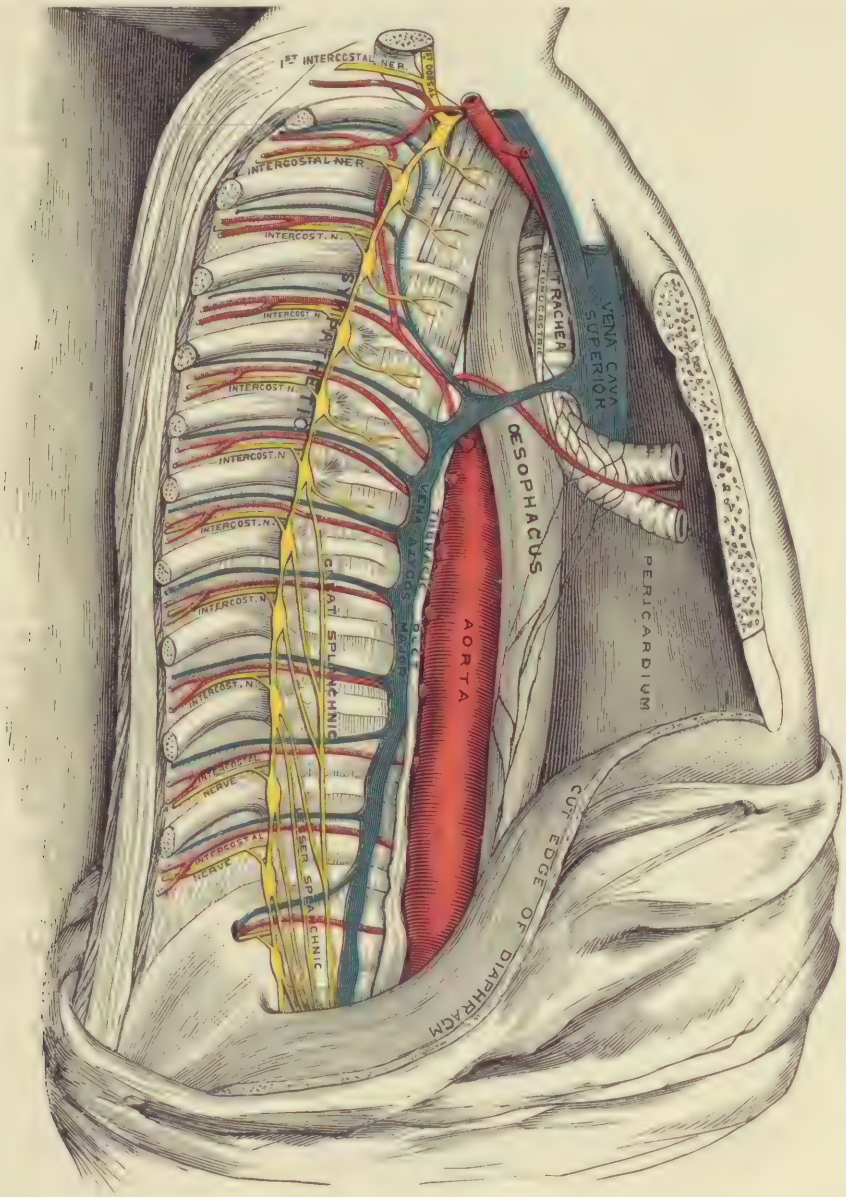

Fig. 988.—The posterior mediastinum.

The Superior Mediastinum (Fig. 989).—The superior mediastinum is that portion of the interpleural space which lies above the upper level of the pericardium, between the manubrium sterni in front and the upper dorsal vertebrae behind. It is bounded below by a plane passing backward from the junction of the manubrium and gladiolus sterni to the lower part of the body of the fourth dorsal vertebra,

and laterally by the lungs and pleurae. It contains the origins of the Sterno-hyoid and Sterno-thyroid muscles and the lower ends of the Longus colli muscles; the arch of the aorta; the innominate, the thoracic portion of the left carotid and subclavian arteries; the upper half of the superior vena cava and the innominate veins, and the left superior intercostal vein; the pneumogastric, cardiac, phrenic, and left recurrent laryngeal nerves; the trachea, œsophagus, and thoracic duct; the remains of the thymus gland and some lymphatic glands.

The Anterior Mediastinum (Fig. 983).—The anterior mediastinum is bounded in front by the sternum, on each side by the pleura, and behind by the pericardium. It is narrow above, but widens out a little below, and, owing to the oblique course taken by the left pleura, it is directed from above obliquely downward and to the left. Its anterior wall is formed by the left Triangularis sterni muscle and the fifth, sixth, and seventh left costal cartilages. It contains a quantity of loose areolar tissue, some lymphatic vessels which ascend from the convex surface of the liver, two or three lymphatic glands (anterior mediastinal glands), and the small mediastinal branches of the internal mammary artery.

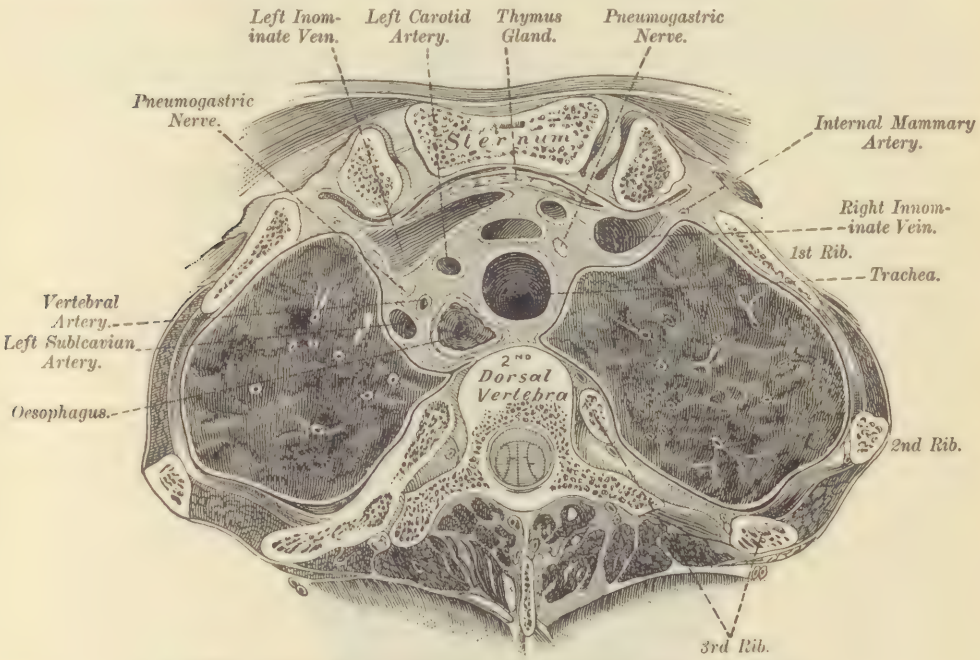

FIG. 989.—Transverse section through the second dorsal vertebra. (Braune.)

The Middle Mediastinum (Fig. 983).—The middle mediastinum is the broadest part of the interpleural space. It contains the heart enclosed in the pericardium, the ascending aorta, the lower half of the superior vena cava, with the vena azygos major opening into it, the bifurcation of the trachea and the two bronchi, the pulmonary artery dividing into its two branches and the right and left pulmonary veins, the phrenic nerves, and some bronchial lymphatic glands.

The Posterior Mediastinum (Figs. 983 and 987).—The posterior mediastinum is an irregular triangular space running parallel with the vertebral column; it is bounded in front by the pericardium and roots of the lungs, behind by the vertebral column from the lower border of the fourth dorsal vertebra, and on either side by the pleura. It contains the descending thoracic aorta, the greater and lesser azygos veins, the pneumogastric and splanchnic nerves, the oesophagus, thoracic duct, and some lymphatic glands.

Blood-vessels.—The areolar tissue of the anterior mediastinum receives numerous **mediastinal branches from the internal mammary artery.** The areolar tissue of the posterior mediastinum receives **mediastinal branches from the descending thoracic aorta.** The lowest mediastinal vessels lie upon the Diaphragm and are called **superior phrenic arteries.** The **vena cava** and **internal mammary veins** receive **mediastinal branches.**

The **anterior mediastinal lymphatic glands** are in the upper portion of the anterior mediastinum. They are five or six in number and are placed in front of the transverse arch of the aorta. Chains of glands run up from them to the root of the neck. On the right side glands are in front of the right innominate vein, between the artery and vein and behind the artery. On the left side they are around the left common carotid and left subclavian arteries.[1]

The **posterior mediastinal glands** are around the oesophagus, particularly in front of it. The **peritracheo-bronchial glands** have been described.

THE LUNGS (PULMONES) (Figs. 983, 990, 991, 992, 993, 994, 995).

The lungs are the essential organs of respiration; they are two in number, placed one on each side of the chest, separated from each other by the heart and other contents of the mediastinum. A healthy lung hangs free within the pleural

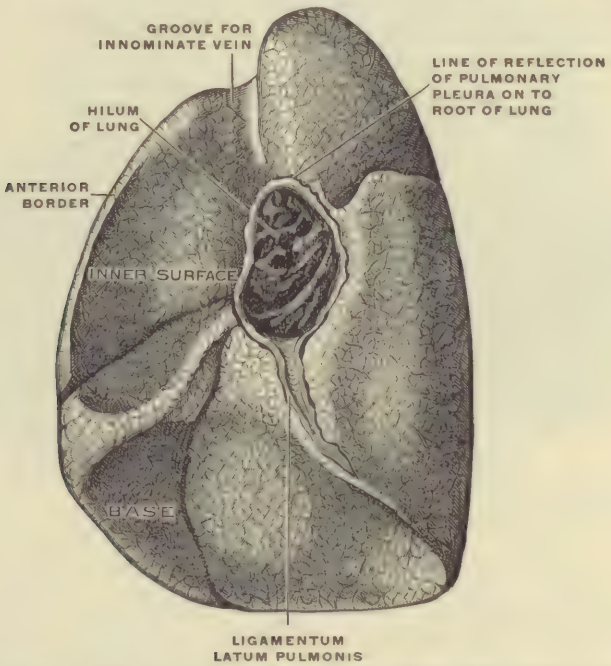

FIG. 990.—The right lung. The inner or mediastinal surface, with the hilum laid bare by the removal of the structures forming the root of the lung. (Toldt.)

cavity. It is suspended by the root and by the ligamentum pulmonis. In many cases examined the lung does not hang free, but, as a result of former pleurisy, an area of the pulmonary pleura is adherent to the parietal pleura. Each lung is conical in shape, and presents for examination an **apex,** a **base,** two **borders,** and two **surfaces.**

The Apex (*apex pulmonis*).—The apex forms a tapering cone which extends into the root of the neck about an inch to two inches above the level of the anterior

[1] Poirier, Cunéo, and Delamare on the Lymphatics. Translated and edited by Cecil H. Leaf.

extremity of the first rib. The brachial plexus is in close proximity to this portion of the lung.

The Base (*basis pulmonis*).—The base is broad, concave, and rests, by its **diaphragmatic surface** (*facies diaphragmatica*), upon the convex surface of the Diaphragm, which separates the right lung from the upper surface of the right lobe of the liver and the left lung from the upper surface of the left lobe of the liver, the fundus of the stomach, and spleen; its circumference is thin, and projects for some distance into the phrenico-costal sinus of the pleura, between the lower ribs and the costal attachment of the Diaphragm, extending lower down externally and behind than in front.

Surfaces. The External, Costal or Thoracic Surface (*facies costalis*) (Figs. 994 and 995).—The external, costal, or thoracic surface is smooth, convex, of considerable extent, and corresponds to the form of the cavity of the chest, being deeper behind than in front. In a hardened specimen this surface has grooves and bulgings on it, corresponding to the ribs and intercostal spaces.

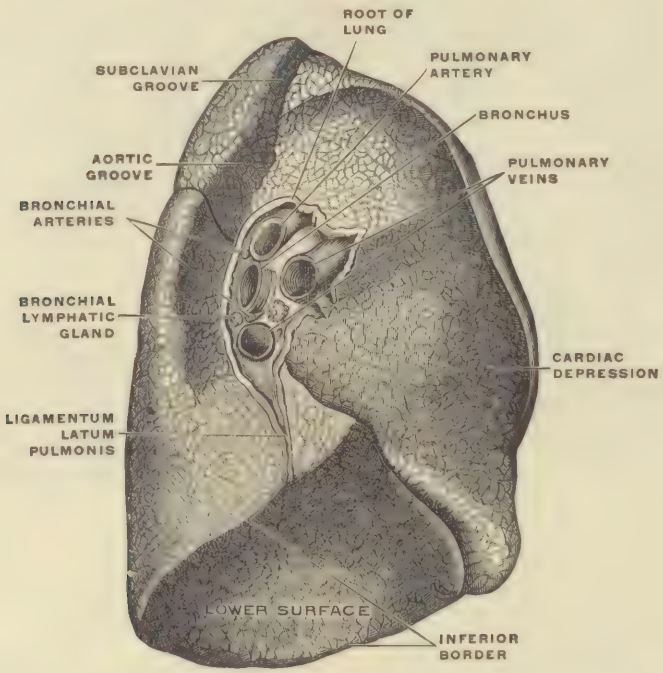

FIG. 991.—The left lung. The inner or mediastinal surface, with the root of the lung cut across. (Toldt.)

The Inner or Mediastinal Surface (*facies mediastinalis*) (Figs. 990 and 991).—The inner or mediastinal surface is concave. It presents in front a depression corresponding to the convex surface of the pericardium, and behind a deep fissure, the **hilum** (*hilus pulmonalis*). In the hilum lie the bronchi, vessels, nerves, and lymph-nodes, which together constitute the **root of the lung**. On the inner and anterior surface, a little below the apex, is a groove, the **subclavian groove** (*sulcus subclavius*), for the subclavian artery. A little lower is a broader and shallower groove for the innominate and subclavian veins. The pleura lies between the lungs and these vessels. In front of the hilum and below it is a depression for the heart (*impressio cardiaca*). It is deeper on the left than on the right side. On the right side it passes into the groove from the superior vena cava and the vena azygos major. On the left side, behind the hilum, is a groove for the thoracic aorta; on the right side a groove for the oesophagus.

Borders. **The Inferior Border** (*margo inferior*).—The inferior border is the line of junction of the costal and diaphragmatic surfaces. Posteriorly, it is rounded and broad, and is received into the deep concavity on either side of the spinal column (Fig. 996). It is much longer than the anterior border, and projects, below, into the phrenico-costal sinus.

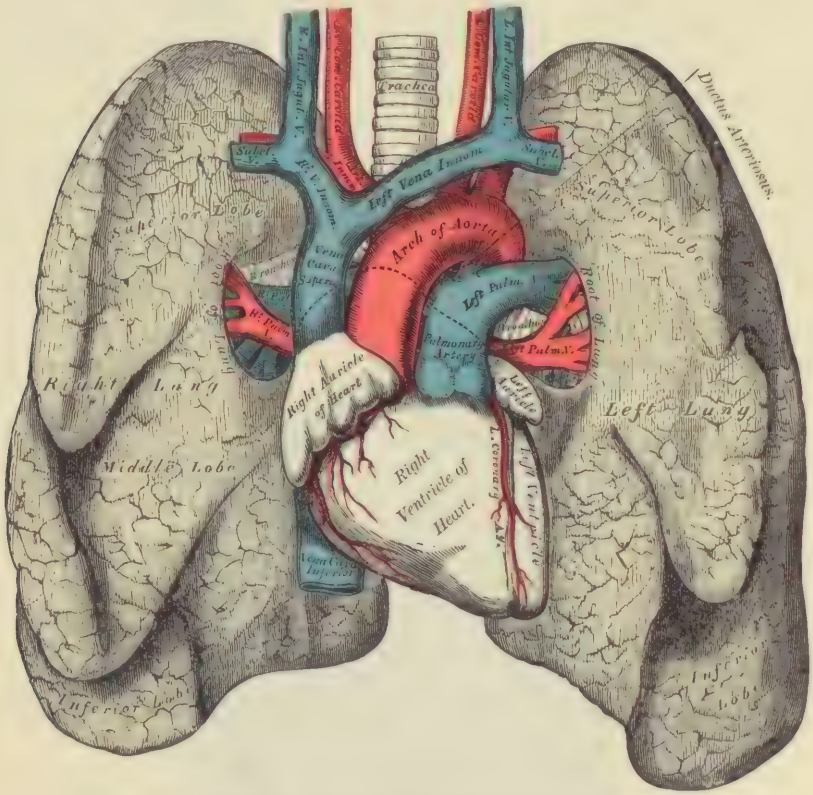

FIG. 992.—Front view of the heart and lungs.

The Anterior Border (*margo anterior*).—The anterior border is thin and sharp, overlaps the front of the pericardium, and is projected into the costo-mediastinal sinus of the pleura. The anterior border of the right lung is almost vertical; that of the left presents, below, an angular notch, the **incisura cardiaca**, into which the heart and pericardium are received. A projection from the upper lobe comes forward beneath the cardiac notch; it is called the **lingula pulmonis**.

The Lobes of the Lungs (Figs. 994 and 995).—Each lung is divided into two lobes, an **upper** (*lobus superior*) and a **lower** (*lobus inferior*), by a long and deep fissure (*incisura interlobaris*), which extends from the upper part of the posterior border of the organ about three inches from its apex, downward and forward to the lowest part of the lung just external to its anterior border. This fissure penetrates nearly to the root. The upper lobe is the smaller; the lower lobe is the larger. In the right lung the upper lobe is partially subdivided by a second and shorter fissure, which extends almost horizontally forward from the middle of the preceding to the anterior margin of the organ, marking off a small triangular portion, the **middle lobe** (*lobus medius*).

The right lung is the larger and heavier; it is broader than the left, owing to the inclination of the heart to the left side; it is also shorter by an inch, in

consequence of the Diaphragm rising higher on the right side to accommodate the liver.

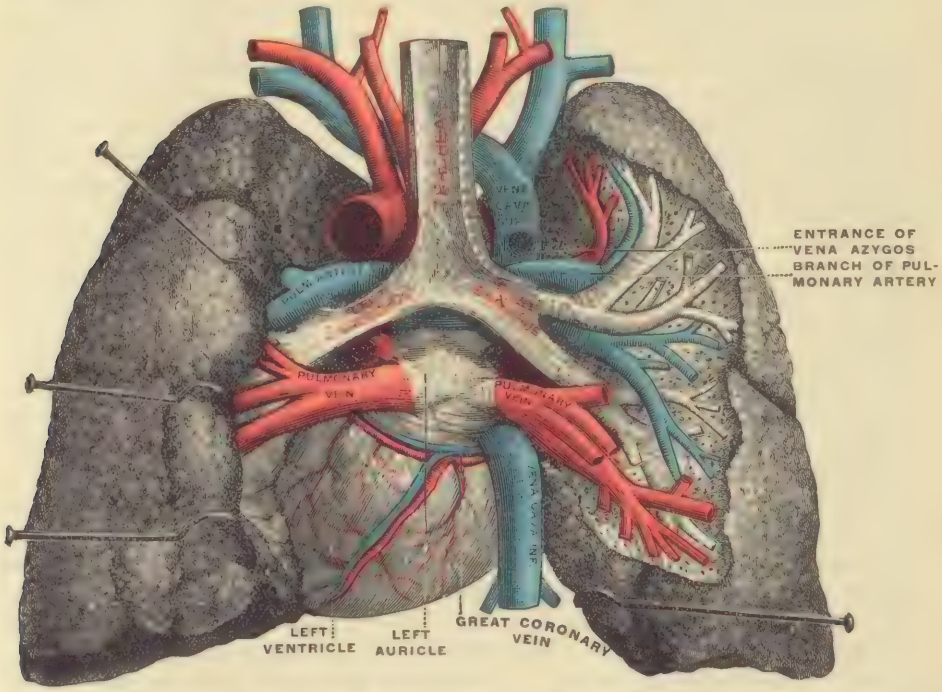

FIG. 993.—Pulmonary veins, seen in a dorsal view of the heart and lungs. The lungs have been pulled away from the median line, and a part of the right lung has been cut away to display the air-ducts and blood-vessels. (Testut.)

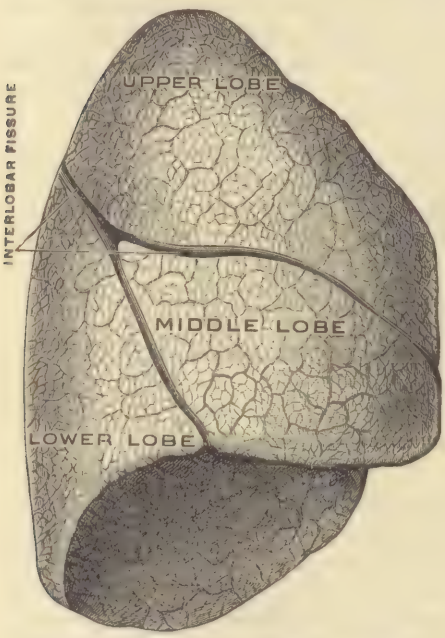

FIG. 994.—The right lung. The outer or costal surface. (Toldt.)

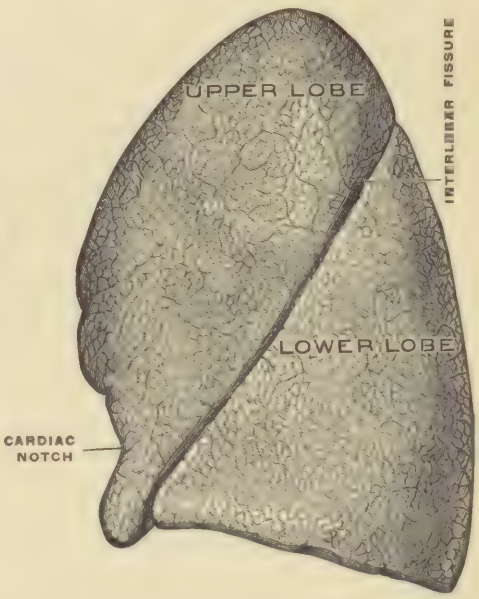

FIG. 995.—The left lung. The outer or costal surface. (Toldt.)

The Root of the Lung (*radix pulmonis*) (Figs. 990, 991, 992, and 993).—A little above the middle of the inner surface of each lung, and nearer its posterior

than its anterior border, is its root, by which the lung is connected to the heart and the trachea. The root is formed by the bronchial tube, the pulmonary artery, the pulmonary veins, the bronchial arteries and veins, the pulmonary plexus of nerves, lymphatics, bronchial glands, and areolar tissue, all of which are enclosed by a reflection of the pleura. The root of the right lung lies behind the superior vena cava and ascending portion of the aorta, and below the vena azygos major. The root of the left lung passes beneath the arch of the aorta and in front of the descending aorta; the phrenic nerve and the anterior pulmonary plexus lie in front of each, and the pneumogastric and posterior pulmonary plexus behind each.

The chief structures composing the root of each lung are arranged in a similar manner from before backward on both sides—viz., the two pulmonary veins in front; the pulmonary artery in the middle; and the bronchus, together with the bronchial vessels, behind. From above downward, on the two sides, their arrangement differs, thus:

On the right side their position is—bronchus, pulmonary artery, pulmonary veins; but on the left side their position is—pulmonary artery, bronchus, pulmonary veins. It should be noted that the entire right bronchus does not lie above the right pulmonary artery, but only its eparterial branch (see p. 1377), which passes to the upper lobe of the right lung; the divisions of the bronchus for the middle and lower lobes lie below the artery.

The **weight** of both lungs together is about forty-two ounces, the right lung being two ounces heavier than the left; but much variation is met with according to the amount of blood or serous fluid they may contain. The lungs are heavier in the male than in the female, their proportion to the body being in the former as 1 to 37, in the latter as 1 to 43. The specific gravity of the lung-tissue varies from 0.345 to 0.746, water being 1.000.

The **color** of the lungs at birth is a pinkish-white; in adult life a dark slate-color, mottled in patches; and as age advances this mottling assumes a black color. The coloring matter consists of granules of a carbonaceous substance deposited in the areolar tissue near the surface of the organ. It increases in quantity as age advances, and is more abundant in males than in females. The posterior surface of the lung is usually darker than the anterior.

The **surface** of the lung is smooth, shining, and marked out into numerous polyhedral spaces, indicating the lobules of the organ; the area of each of these spaces is crossed by numerous lighter lines.

The **substance** of the lung is of a light, porous, spongy texture; it floats in water and crepitates when handled, owing to the presence of air in the tissue; it is also highly elastic; hence the collapsed state of these organs when they are removed from the closed cavity of the thorax.

The Fœtal Lung.—After respiration has been established, the lung fills the pleural cavity. In the fœtus, as the lung has never been distended with air and has never received a large amount of blood, it is gathered into a small mass at the back of the thorax. It will sink in water and feels solid to the touch.

Structure.—The structure of the lung is such that the blood brought by the pulmonary artery comes into close relation with the air which enters from the bronchioles. The blood gives materials to the air, and the air gives elements to the blood, and the process of respiration causes the dark blood brought from the heart by the pulmonary artery to return to the heart as red blood in the pulmonary vein. The lungs are composed of an **external serous coat, a subserous areolar tissue**, and the **pulmonary substance** or **parenchyma.**

The Serous Coat.—The serous coat is thin, transparent, and invests the entire organ as far as the root. It is known as the pulmonary pleura (p. 1384).

The Subserous Areolar Tissue.—The subserous areolar tissue contains a large proportion of elastic fibres; it invests the entire surface of the lung, and extends inward between the lobules, and at the hilum forms the pulmonary scaffold or framework.

The Parenchyma.—The parenchyma is composed of **lobules** which, although closely connected together by an interlobular areolar tissue, are quite distinct from one another, and may be teased asunder without much difficulty in the fœtus. The lobules vary in size; those on the surface are large, of pyramidal form, with the bases turned toward the surface; those in the interior are smaller and of various forms. Each lobule is composed of one of the ramifications of a bronchial tube and its terminal air-cells, and of the ramifications of the pulmonary and bronchial vessels, lymphatics, and nerves, all of these structures being connected together by areolar tissue.

The Bronchus (pp. 1377 and 1378) (Figs. 980, 981, and 982).—The bronchus, upon entering the substance of the lung, divides and subdivides bipinnately, throughout the entire organ. Sometimes three branches arise together, and occasionally small lateral branches are given off from the sides of a main trunk. Each of the smaller subdivisions of the bronchi enters a pulmonary lobule, and is termed a **lobular bronchial tube** or **bronchiole** (*bronchioli*). Each bronchiole divides into minute branches (*bronchioli respiratorii*), the walls of which now begin to present irregular dilatations, **bronchial alveoli.** These are present at first sparingly and on one side of the tube only, but as it proceeds onward these dilatations become more numerous and surround the tube on all sides, so that it loses its cylindrical character. The terminal branches come from the bronchioli respiratorii. These terminal branches are called the **alveolar ducts** or **alveolar passages** (*ductuli alveolares*). The alveolar ducts show numerous alveoli (Fig. 981) and join with cavities called **atria.** Each atrium joins several larger cavities, the **air-cells** or **air-sacs** (*infundibula*). The numerous small cavities on the surface of the air-sacs are the **pulmonary alveoli** (*alveoli pulmonis*). The bronchiole now becomes widened out and terminates in an irregular cul-de-sac, the **air cell, air sac alveolus** or **infundibulum.** The walls of the infundibulum are closely beset in all directions by **pulmonary alveoli** or **pulmonary air cells.** Professor Gerrish remarks that the first of the alveoli seen on the bronchioles before the coreal ends are formed would seem an effort on the part of nature to form an infundibulum before all the necessary conditions are favorable.

Changes in the Structure of the Bronchi in the Lungs.—Within the lungs the bronchial tubes are circular, not flattened (Fig. 982), and present certain peculiarities of structure.

In the Lobes of the Lungs.—In the lobes of the lungs the following changes take place: The **cartilages** are not imperfect rings, but consist of thin laminæ, of varied form and size, scattered irregularly along the sides of the tube, being most distinct at the points of division of the bronchi. They may be traced into tubes, the diameter of each of which is only one-fourth of a line. Beyond this point the tubes are wholly membranous. The **fibrous coat** is continued into the smallest ramifications of the bronchi. The **muscular coat** is disposed in the form of a continuous layer of annular fibres, which may be traced upon the smallest bronchial tubes, and consists of the unstriped variety of muscular tissue. The **mucous membrane** lines the bronchi and their ramifications throughout, and is covered with columnar ciliated epithelium.

In the Lobules of the Lung.—In the lobular bronchial tubes and in the infundibula the following changes take place: The **muscular tissue** begins to disappear, so that in the infundibula there is scarcely a trace of it. The **fibrous coat** becomes thinner, and degenerates into areolar tissue. The **epithelium** becomes non-ciliated and flattened. This occurs gradually; thus, in the lobular bronchioles

patches of non-ciliated flattened epithelium may be found scattered among the columnar ciliated epithelium; then these patches of non-ciliated flattened epithelium become more and more numerous, until in the infundibula and air-cells all the epithelium is of the non-ciliated pavement variety. In addition to these flattened cells, there are small polygonal granular cells in the air-sacs, in clusters of two or three, between the others.

The air-cells are small, polyhedral recesses composed of a fibrillated connective tissue and surrounded by a few involuntary muscular and elastic fibres. Free in their cavity are to be seen under the microscope granular, rounded, amœboid cells (eosinophile leukocytes), often containing carbonaceous particles. The air-cells are well seen on the surface of the lung, and vary from $\frac{1}{200}$ to $\frac{1}{70}$ of an inch in diameter, being largest on the surface at the thin borders and at the apex, and smallest in the interior.

Mucous Glands.—In the larger bronchi the mucous membrane contains goblet cells. When the tubes diminish to 1 mm. in diameter the glands grow fewer. In the smaller bronchi there are no mucous glands.

Vessels of the Lungs.—The **pulmonary artery** (Figs. 992 and 993) conveys the venous blood to the lungs; it divides into branches which accompany the bronchial tubes, and terminates in a dense capillary network upon the walls of the intercellular passages and air-cells. In the lung the branches of the pulmonary artery are usually above and in front of a bronchial tube, the vein below.

The **pulmonary capillaries** form plexuses which lie immediately beneath the mucous membrane in the walls and septa of the air-cells and of the infundibula. In the septa between the air-cells the capillary network forms a single layer. The capillaries form a very minute network, the meshes of which are smaller than the vessels themselves;[1] their walls are also exceedingly thin. The arteries of neighboring lobules are independent of each other, but the veins freely anastomose together.

The **pulmonary veins** commence in the pulmonary capillaries, the radicles coalescing into larger branches, which run along through the substance of the lung, independently from the minute arteries and bronchi. After freely communicating with other branches they form large vessels, which ultimately come into relation with the arteries and bronchial tubes, and accompany them to the hilum of the organ. Finally they open into the left auricle of the heart, conveying oxygenated blood to be eventually distributed to all parts of the body by the aorta.

The **bronchial arteries** supply blood for the nutrition of the lung. The thoracic aorta usually gives off two left bronchial arteries. The single right bronchial artery usually arises from the first right aortic intercostal, but sometimes from the superior left bronchial artery, or from the aorta. In the root of the lung they are posterior to the bronchus, they accompany the bronchial tubes, supply the tubes and pulmonary tissue, and give branches to the walls of the larger pulmonary vessels, the oesophagus, pericardium, and bronchial glands. Those supplying the bronchial tubes form a capillary plexus in the muscular coat, from which branches are given off to form a second plexus in the mucous coat. This plexus communicates with branches of the pulmonary artery, and empties itself into the pulmonary vein. Others are distributed in the interlobular areolar tissue, and terminate partly in the deep, partly in the superficial, bronchial veins. Lastly, some ramify upon the surface of the lung beneath the pleura, where they form a capillary network. There may be but one bronchial artery; there may be three or four.

The **bronchial veins** are not found in the walls of the very small bronchi. The small bronchial veins run along by the front and back of the median sized and

[1] The meshes are only 0.002‴ to 0.008‴ in width, while the vessels are 0.003‴ to 0.005‴ (Kölliker, Human Microscopic Anatomy).—Ed. of 15th English edition.

larger tubes, and from two trunks at the root of each lung. These vessels terminate on the right side in the vena azygos major, and on the left side in the superior intercostal or left upper azygos vein. Tracheal and posterior mediastinal veins open into the bronchial veins. The venous blood from the smaller tubes passes to the pulmonary veins.

The **lymphatics** begin in networks about the lobules and form networks about the bronchi and beneath the bronchial mucous membrane. The superficial collecting trunks arise about the lobules and beneath the pleura. According to Sappey, the superficial trunks from the upper lobe begin on the costal surface; one set passes around the anterior border, another set around the posterior border, and a third into the incisura interlobaris. The same observer says that the superficial trunks from the middle lobe unites with the trunks from the upper and lower lobes; and the superficial trunks from the lower lobe, like those of the upper lobe, are in three sets. One set passes around the posterior margin, one around the anterior margin, and one into the incisura interlobaris. All of the superficial trunks convey lymph to the glands of the hilum. Some of the deep collecting trunks begin by the sides of the small bronchi; others course along by the pulmonary veins or pulmonary arteries. All of them pass to the glands of the hilum. The glands of the hilum are in communication with the peritracheo-bronchial glands.[1]

Nerves.—The lungs are supplied from the **anterior** and **posterior pulmonary plexuses,** formed chiefly by branches from the **sympathetic** and **pneumogastric.** The filaments from these plexuses accompany the bronchial tubes, and are lost upon them. Small ganglia are found upon these nerves.

Surface Form.—The apex of the lung is situated in the neck, behind the interval between the two heads of origin of the Sterno-mastoid muscle. The height to which it rises above the clavicle varies very considerably, but is generally about one inch. It may, however, extend as much as an inch and a half or an inch and three-quarters, or, on the other hand, it may scarcely project above the level of this bone. In order to mark out the anterior margin of the lung, a line is to be drawn from the apex-point, one inch above the level of the clavicle, and rather nearer the posterior than the anterior border of the Sterno-mastoid muscle, downward and inward across the sterno-clavicular articulation and first piece of the sternum until it meets, or almost meets, its fellow of the other side opposite the articulation of the manubrium and gladiolus. From this point the two lines are to be drawn downward, one on either side of the mesial line and close to it, as far as the level of the articulation of the fourth costal cartilages to the sternum. From here the two lines diverge; the left is to be drawn at first passing outward with a slight inclination downward, and then taking a bend downward with a slight inclination outward to the apex of the heart, and thence to the sixth costo-chondral articulation. The direction of the anterior border of this part of the left lung is denoted with sufficient accuracy by a curved line with its convexity directed upward and outward from the articulation of the fourth right costal cartilage of the sternum to the fifth intercostal space, an inch and a half below and three-quarters of an inch internal to the left nipple. The continuation of the anterior border of the right lung is marked by a prolongation of its line from the level of the fourth costal cartilages vertically downward as far as the sixth, when it slopes off along the line of the sixth costal cartilage to its articulation with the rib.

The lower border of the lung is marked out by a slightly curved line with its convexity downward from the articulation of the sixth costal cartilage to its rib to the spinous process of the tenth dorsal vertebra. If vertical lines are drawn downward from the nipple, the mid-axillary line, and the apex of the scapula, while the arms are raised from the sides, they should intersect this convex line, the first at the sixth, the second at the eighth, and the third at the tenth rib. It will thus be seen that the pleura extends farther down than the lung, so that it may be wounded, and a wound may pass through its cavity into the Diaphragm, and the abdominal viscera may be injured without the lung being involved.

The posterior border of the lung is indicated by a line drawn from the level of the spinous process of the seventh cervical vertebra, down either side of the spine, corresponding to the costo-vertebral joints as low as the spinous process of the tenth dorsal vertebra. The trachea bifurcates opposite the spinous process of the fourth dorsal vertebra, and from this point the two bronchi are directed outward.

"The position of the great fissure of the lungs may be indicated by a line drawn from the third

[1] The Lymphatics, by Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.

dorsal spine obliquely downward in such a manner as to reach the sixth rib close to the mid-clavicular line. The interlobar fissure between the upper and middle lobes of the right lung corresponds to a line drawn from the apex of the axilla almost horizontally to the sternum, reaching the latter at about the level of the fourth costal cartilage" (Erendrath).

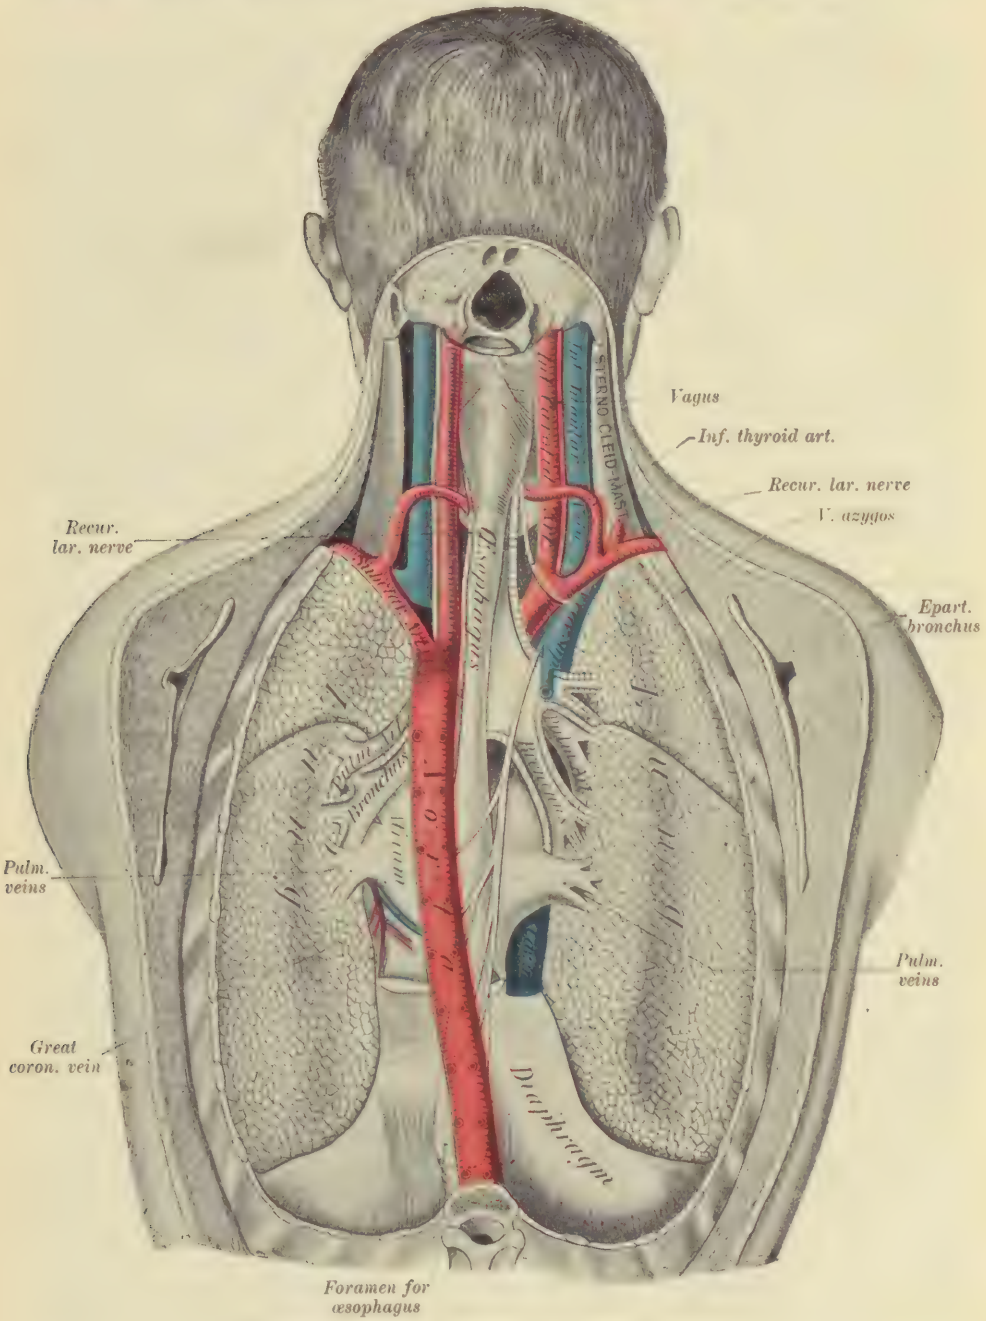

FIG. 996.—Thoracic contents seen from behind. (Joessel.)

Surgical Anatomy.—The lungs may be wounded or torn in three ways: (1) By compression of the chest, without any injury to the ribs. (2) By a fractured rib penetrating the lung. (3) By stabs, gunshot wounds, etc.

The first form, where the lung is *ruptured by external compression* without any fracture of the ribs, is very rare, and usually occurs in young children, and affects the root of the lung—*i. e.*, the most fixed part—and thus, implicating the great vessels, is frequently fatal. It would seem to be a most unusual injury, and the exact mode of its causation is difficult to understand. The probable explanation is that immediately before the compression is applied a deep inspiration is taken and the lungs are fully inflated; owing then to spasm of the glottis at the moment of compression, the air is unable to escape from the lung, the lung is not able to recede, and consequently gives way.

In the second variety, when the *wound* in the lung is produced by the *penetration of a broken rib*, both the pleura costalis and the pleura pulmonalis must necessarily be injured, and consequently the air taken into the wounded air-cells may find its way through these wounds into the cellular tissue of the parietes of the chest. This it may do without collecting in the pleural cavity; the two layers of the pleura are so intimately in contact that the air may pass straight through from the wounded lung into the subcutaneous tissue. *Emphysema* constitutes, therefore, an important sign of injury to the lung in cases of fracture of the ribs. *Pneumothorax*, or air in the pleural cavity, is much more likely to occur in injuries to the lung of the third variety; that is to say, from *external wounds*, from stabs and gunshot injuries, in which cases air passes either from the wound of the lung or from an external wound into the cavity of the pleura during the respiratory movements. In these cases there is generally no emphysema of the subcutaneous tissue unless the external wound is small and valvular, so that the air drawn into the wound during inspiration is then forced into the cellular tissue around during expiration because it cannot escape from the external wound. Occasionally in wounds of the parietes of the chest no air finds its way into the cavity of the pleura, because the lung at the time of the accident protrudes through the wound and blocks the opening. This occurs where the wound is large, and constitutes a so-called *hernia* of the lung. *True hernia* of the lung occurs, though very rarely, after wounds of the chest-wall, when the wound has healed and the cicatrix subsequently yields from the pressure of the viscus behind. It forms a globular, elastic, crepitating swelling, which enlarges during expiratory efforts, falls during inspiration, and disappears on holding the breath. Wounds of the lung may produce dangerous or fatal *hemorrhage* into the pleural sac. In many cases the bleeding is spontaneously arrested; in others the surgeon must interfere to save life. In some cases air has been admitted by intercostal incision and the insertion of a tube, and pulmonary collapse has arrested bleeding. In other cases it is necessary to resect portions of several ribs, and stop bleeding by ligatures or suture ligatures. In one case of a furious secondary hemorrhage following a gunshot wound, the editor resected several ribs, packed the pleural cavity about the lung with sterile gauze, to obtain a base of support, and then arrested the bleeding by packing iodoform gauze against the firmly supported lung. This patient recovered.

Incision of the lung (*pneumotomy*) is performed for pulmonary abscess (either tuberculous or pyogenic), pulmonary gangrene, hydatid cysts, and bronchiectasis. In pulmonary abscess, locate the area by physical signs and the *x*-ray, resect a portion of a rib over it, and note if the pleura is adherent. If it is adherent, continue the operation. If it is not adherent, insert stitches of catgut through the two layers of pleura and the superficial part of the lung, so as to encircle a considerable area, and then wait several days for adhesions to form. Adhesions protect the pleura from infection, and, by keeping air from the pleural sac, prevent pneumothorax. When ready to continue the operation, locate the abscess with an aspirating-needle and syringe, open it with a cautery at a dull-red heat, and drain by means of a tube.

Pneumotomy is very unsatisfactory in tuberculous cavities and bronchiectasis. In tuberculosis, excision of the diseased area (*pneumectomy*) has been employed, but it is not to be advised.

THE DUCTLESS GLANDS.

THESE glands do not possess excretory ducts. They furnish materials which are added to the blood or lymph as it passes through them. The material from each gland is known as an **internal secretion.** Some of these secretions are powerful materials and influence profoundly the body nutrition. The ductless glands are usually given as follows: the **spleen**, the **lymphatic glands**, the **pineal gland**, the **pituitary body**, the **suprarenal capsules**, the **thyroid gland**, the **para-thyroids**, the **thymus**, the **carotid body**, and the **coccygeal body.** The **lymphatic glands** were described in a special section (p. 772). The lymphatic glands are not considered to be really glands, but, nevertheless, as lymph passes through the lymph glands, it receives a product of the glands, namely, lymphocytes. There is no evidence that the **spleen** furnishes an active internal secretion, and this organ has been studied with the abdominal viscera. The **pineal gland** (p. 905) and **pituitary body** (p. 882) were considered with the brain. The **suprarenal capsules** (p. 1428) are described with the kidneys. Some glands, for instance, the **liver, pancreas** and **testicle,** have an external secretion and also an internal secretion.

THE THYROID BODY OR GLAND (GLANDULA THYREOIDEA) (Fig. 997).

The thyroid gland is an extremely vascular body, situated at the front and sides of the neck, and extending upward upon each side of the larynx. It is a single gland, varying greatly in size in different individuals. It is larger relatively in females and in children than in men. It is frequently asymmetrical. In early embryonal life the gland has a duct, the **thyro-glossal duct** (*ductus thyreoglossus*), which passes from the isthmus of the thyroid to the foramen caecum of the dorsum of the tongue. The lumen of this duct is obliterated early and becomes a cord of epithelium. The lower portion of the duct often remains open for a little way. The upper portion remains as the foramen caecum. The situation of this obliterated fœtal duct may be marked by the **third** or **middle lobe** of the thyroid gland. The thyroid surrounds the upper portion of the trachea like a horseshoe. It consists of two lateral lobes connected across the middle line by a narrow transverse portion, the **isthmus.**

The **weight** of the gland is somewhat variable, but is usually about one ounce. It is somewhat heavier in the female, in whom it becomes enlarged during menstruation and pregnancy. As age advances the weight of the thyroid diminishes.

The **color** of the thyroid, as seen from the surface, is reddish-blue. The gland is surrounded by a closely adherent thin connective-tissue capsule of the **pre-tracheal layer of deep cervical fascia.** From the inner surface of the capsule come delicate septa, which enter into the thyroid body and separate it into lobes and also separate the lobes into lobules. The blood-vessels lie beneath the capsule. The anterior and lateral portions of the gland are covered by the capsule. "Passing around the side of the gland to its posterior surface, this capsule then splits into two portions. One remains in contact with the gland and invests its posterior surface. The other, the thicker of the two, passes to the posterior surface of the pharynx

and oesophagus, thus enclosing them with the larynx, trachea, and thyroid gland, in a common sheath."[1]

The **lateral lobes** are conical in shape, the apex of each being directed upward and outward as far as the junction of the middle with the lower third of the thyroid cartilage; the base looks downward, and is on a level with the fifth or sixth tracheal ring. The summit of the lateral lobe not unusually is pointed and reaches to the level of the oblique line upon the ala of the thyroid cartilage or even higher. The right is, as a rule, somewhat larger than the left lobe. The lower portion of the gland, when the head is extended, is about one inch above the upper margin of the sternum; when the head is flexed, it is at the level of the upper border of the sternum or even below and behind it. The portion of the lateral lobe above the level of the superior border of the isthmus is called the **upper horn,** the portion below the level of the inferior margin of the isthmus is called the **lower horn.** The lower horn "is usually much smaller than the upper horn; frequently it is altogether absent."[2] At the inner and posterior part of each lateral lobe is the **hilum.** At the hilum the inferior thyroid artery passes into the gland. "Here the **recurrent laryngeal nerve** comes into close contact with the gland, lying in the space between it and the trachea and oesophagus."[3]

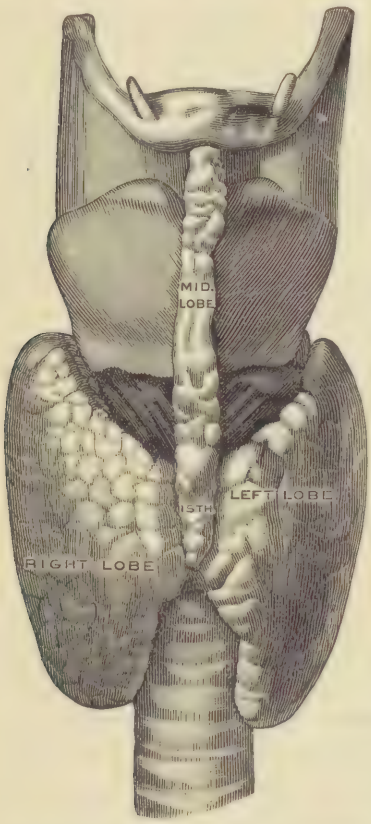

FIG. 997.—The thyroid gland. (Spalteholz.)

The **external** or **superficial surface** is convex, and covered by the skin, the superficial fascia, the deep fascia, the Sterno-mastoid, the anterior belly of the Omo-hyoid, the Sterno-hyoid and Sterno-thyroid muscles, and beneath the last-named muscles by the pre-tracheal layer of the deep fascia, which forms a capsule for the gland.

The **deep** or **internal surface** is moulded over the underlying structures—viz., the thyroid and cricoid cartilages, the trachea, the inferior constrictor and posterior part of the Crico-thyroid muscles, the oesophagus (particularly on the left side of the neck), the superior and inferior thyroid arteries, and the recurrent laryngeal nerves.

The deep surface of each lobe is fixed by bands of fibrous tissue passing from the capsule of the isthmus and lateral lobes to the sides of the cricoid cartilage and the posterior fascia of the trachea. These bands are called the **lateral** or **suspensory ligaments.** Because of this fixation to the larynx and trachea by the capsule and by the lateral ligaments, the thyroid gland moves with the trachea and ascends during the act of swallowing. The recurrent laryngeal nerve on each side is in contact with the outer and posterior surface of the suspensory ligament.

The **anterior border** is thin, and inclines obliquely from above downward and inward toward the middle line of the neck, while the **posterior border** is thick and overlaps the common carotid artery. Each lobe is about two inches in length, its greatest width is about one inch and a quarter, and its thickness about three-quarters of an inch. The posterior border is over the common carotid artery and

[1] Diseases of the Thyroid Gland. By James Berry. [2] Ibid. [3] Ibid.

touches the œsophagus and pharynx. The carotid artery usually makes a groove upon the gland.

The Isthmus (*isthmus glandulae thyreoidea*).—The isthmus connects the lower third of the two lateral lobes; it measures about half an inch in breadth and the same in depth, and usually covers the second and third rings of the trachea, but sometimes also the first and fourth rings. Its situation presents, however, many variations, a point of importance in the operation of tracheotomy. In the middle line of the neck it is covered by the skin and fascia, and close to the middle line, on either side, by the Sterno-hyoid muscle. Across its upper border run branches of the superior thyroid artery and vein; at its lower border is a branch of the inferior thyroid veins. Sometimes the isthmus is altogether wanting, the two lateral lobes being completely separate.

The **third, pyramidal** or **middle lobe** is called the **pyramid of Lalouette.** It is not constant, but is frequently found. Occasionally it arises from the upper part of the isthmus, or from the adjacent portion of either lobe, but most commonly from the left lobe, and ascends in front of the thyroid cartilage in the direction of the middle of the hyoid bone. It may reach the bone or may not reach it. If it reaches the bone it is attached to it. If it does not reach the bone, fibrous tissue, which often contains muscle, is prolonged from the tip of the pyramid to the back of the bone or to the thyro-hyoid membrane. The pyramid is occasionally quite detached, or divided into two or more parts, or altogether wanting.

A few muscular bands, derived from the Thyro-hyoid muscles, are occasionally found attached, above, to the body of the hyoid bone, and below to the isthmus of the gland or its pyramidal process. These form a muscle, which was named by Soemmerring the **Levator glandulae thyreoidae.**

Accessory Thyroids (*glandulae thyreoideae accessoriae*).—Frequently small isolated masses of thyroid tissue exist. They are found particularly about the lateral lobes of the thyroid gland in the sides of the neck or just above the hyoid bone, and are called **accessory thyroids.** Accessory thyroids may also exist by the side of the pyramidal lobe or upon the trachea, as low even as the level of the arch of the aorta. These isolated portions of gland tissue represent isolated portions of the median thyroid rudiment. Sometimes accessory thyroid tissue is found in the root of the tongue or in the interior of the larynx. Berry points out that a distinction must be made between true congenital accessory thyroids and masses of encapsuled thyroid tissue which "have been extruded from the gland."

Structure of the Thyroid (Fig. 998).—The thyroid body is invested by a thin capsule of connective tissue which projects into its substance as a framework and imperfectly divides it into masses of irregular form and size, known as lobules. More slender septa separate the secretory alveoli from one another. When the organ is cut into, it is of a brownish-red color, and is seen to be made up of a number of closed vesicles or alveoli containing a yellow glairy fluid and separated from each other by intermediate connective tissue.

According to Baber, who has published some important observations on the minute structure of the thyroid,[1] the vesicles of the thyroid of the adult animal are generally closed cavities; but in some young animals (*e. g.*, young dogs) the vesicles are more or less tubular and branched. This appearance he supposes to be due to the mode of growth of the gland, and merely indicating that an increase in the number of vesicles is taking place. Each vesicle is lined by a single layer of epithelium, the cells of which are cubical or cylindrical. Between the epithelial cells exists a delicate reticulum. The vesicles are of various sizes and shapes, and contain as a normal product a viscid, homogeneous, semi-fluid, slightly yellowish material which frequently contains blood, the red corpuscles of

[1] Researches on the Minute Structure of the Thyroid Glands, Phil. Trans., part iii., 1881

which are found in it in various stages of disintegration and decolorization, the yellow tinge being probably due to the hæmoglobin, which is thus set free from the colored corpuscles. This normal product is known as **colloid material**, and it is secreted by the epithelium. What part if any the colloid plays in the formation of the internal secretion of the gland is not known. It is quite possible that the colloid corresponds to the external secretion of glands with ducts and that the true internal secretion passes directly into the capillaries which form a network about the alveoli (Szymonowicz), or passes into the lymphatics. In the thyroid gland of the dog, Baber has found large round cells, **parenchymatous cells**, each provided with a single oval-shaped nucleus, which migrate into the interior of the gland-vesicles. Between the thyroid vesicles in the human being are collections of **round cells**. They are, in reality, miniature vesicles, and are much more numerous in youth than in old age.

The capillary blood-vessels form a dense plexus in the connective tissue around the vesicles, between the epithelium of the vesicles and the endothelium of the **lymph-spaces**, which latter surround a greater or smaller part of the circumference

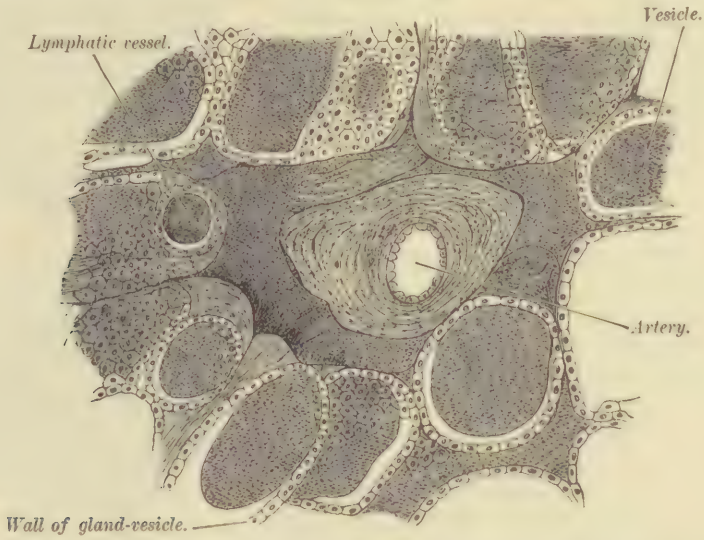

FIG. 998.—Minute structure of the thyroid. From a transverse section of the thyroid of a dog. Semi-diagrammatic. (Baber.)

of the vesicles. These lymph-spaces empty themselves into **lymphatic vessels** which run in the interlobular connective tissue, not uncommonly surrounding the arteries which they accompany, and communicate with a network in the capsule of the gland. Small glands may be connected with this network. Baber has found in the lymphatics of the thyroid a viscid material which is morphologically identical with the normal constituent of the vesicle.

Vessels and Nerves.—The **arteries** (Figs. 392 and 393; see also p. 602) supplying the thyroid are the **superior thyroid** from the **external carotid**, and the **inferior thyroid** from the **thyroid axis** of the first part of the subclavian. Sometimes there is an additional vessel, the **thyroidea media** or **ima**, usually arising from the innominate artery, but sometimes from the arch of the aorta or the common carotid. It ascends upon the front of the trachea. The superior thyroid artery reaches the summit of the upper horn of the gland, and usually at this point gives off a vessel which courses down the posterior surface of the gland. The main trunk passes downward and inward at the junction of the inner and anterior border of the upper horn, giving branches to adjacent structures and sending branches over

the anterior surface of the thyroid gland. It reaches the isthmus and crosses the isthmus at its upper border to anastomose with the artery from the other side. The inferior thyroid artery, which is usually larger than the superior, after it has passed posterior to the sheath of the carotid and the sympathetic nerve, reaches the posterior surface of the gland. At this point branches are given off; some pass into the hilum; the others go to the posterior surface of the gland. The relation of the artery to the recurrent laryngeal nerve is very important to the surgeon. "Usually the main trunk of the artery passes behind the nerve; sometimes the artery breaks up before reaching the nerve; in this case one or more of the branches may pass in front of it. Much less commonly the main trunk or all its branches will be found to lie in front of the nerve."[1] If the thyroidea ima is present it goes to the lower part of the gland. The larger branches of the thyroid arteries are beneath the capsule and upon the surface of the gland; smaller branches pass to the interior of the gland (Berry). The arteries are remarkable for their large size and frequent anastomoses.

The **thyroid veins** (Figs. 447 and 448; see also p. 731) form a plexus upon the surface of the gland and beneath the capsule. Here and there veins pass through the capsule and go to adjacent venous trunks. Berry, accepting Kocher's description, notes the following veins: The **superior thyroid vein** runs with the superior thyroid artery and passes to the internal jugular vein. A **transverse vein** of the upper border of the isthmus joins the two superior thyroid veins. A single vein, the **middle thyroid,** sometimes emerges from the side of the gland and passes to the internal jugular. Usually, however, instead of this single vein there are two veins, the **superior** and **inferior accessory thyroids.** The **superior accessory thyroid** emerges from the outer side of the upper horn, below the apex, and passes to the internal jugular. The **inferior accessory thyroid** emerges from the posterior and inferior portion of the gland and passes to the internal jugular. The veins from the lower border of the gland vary greatly. A vein passes vertically down on each side in front of the trachea from the isthmus and from the inner side of the inferior horn. It is called by Kocher the **thyroidea ima.** The vein of the left side passes to the left innominate; the vein of the right side passes to the right innominate or left innominate. As Berry points out, the vein of one side may be small or may be absent, or the two veins may unite and form one vein which enters the left innominate. An **inferior thyroid vein** is often present. It is of small size, emerges at the inferior and external part of the gland, and passes to the corresponding innominate vein.[2]

The **lymphatics** are numerous and of large size. Collecting trunks arise from a network within the capsule. Some trunks ascend from the upper margin of the isthmus and reach the **gland in front of the larynx**; others ascend along the superior thyroid artery and reach the **glands at the bifurcation of the carotid.** Descending trunks from the lower margin of the isthmus reach the **glands in front of the trachea**; trunks from the side of the gland descend to the **glands about the recurrent laryngeal nerve.**[3]

The **nerves** are derived from the **middle** and **inferior cervical ganglia of the sympathetic,** and from the **inferior laryngeal nerves.** Probably there is also a branch from each **superior laryngeal nerve.**

Surgical Anatomy. The thyroid gland may be congenitally absent, and when it is the individual suffers from the worst form of *cretinism.* One lobe may be congenitally absent, but this will provoke no trouble unless the other lobe undergoes atrophy.

Complete removal of the thyroid and parathyroids will produce operative *myxœdema* (*cachexia strumipriva*), unless accessory thyroids enlarge and perform the functions of the thyroid.

The thyroid gland may be congenitally enlarged. The gland tends to atrophy in old age. It is atrophied in myxœdema and cretinisin. Some forms of thyroid enlargement are called *goitre.*

[1] Diseases of the Thyroid Gland. By James Berry. [2] Ibid.
[3] The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.

When all parts of the gland enlarge the condition is known as *parenchymatous goitre*.

Adenomatous goitre consists of an adenoma or of adenomata. In *cystic goitre* there is one or more cysts due to cystic degeneration of adenomata or to fusion of adjacent follicles.

A *pulsating goitre* is one which receives impulses from the carotid pulsations. In a *fibroid goitre* there is increase of interstitial connective tissue. A goitre which passes back of the sternum is known as *substernal* or *intrathoracic*. A goitre may extend back of the trachea or back of the oesophagus.

Exophthalmic goitre, Graves's disease or Basedow's disease, is a remarkable disease. Its three chief symptoms are enlargement of the thyroid, or *goitre*; prominence of the eyeballs, or *exophthalmos*, and very rapid pulse, or *tachycardia*. Dyspnœa, tremor, and various other symptoms are usually found. The thyroid gland may be the seat of a *carcinoma* or *sarcoma* (*malignant goitre*), *syphilitic* or *tuberculous* disease, ordinary *inflammation*, *suppuration*, or *hydatid disease*; For the relief of ordinary goitre various methods have been employed. Tapping, injection of astringents, simple incision, and the seton are obsolete. Ligature of the thyroid arteries is rarely performed as a curative measure. The superior and inferior thyroids of one side have been tied in some cases; all four thyroids in other cases. Jaboulay has performed *exothyropexy*. In this operation the gland is dislocated from its bed, brought out of the wound, and left exposed, in hope that it will atrophy

Division of the isthmus is occasionally practised to relieve dyspnœa. The operation sometimes succeeds, but often fails.

Extirpation of one-half or two-thirds of the gland is a very successful operation. Removal of the entire gland with the parathyroids will be followed by operative myxœdema.

In *extirpating* a lobe of the thyroid great care must be taken to avoid tearing the capsules, as if this happens the gland-tissue bleeds profusely. The thyroid arteries should be ligatured on the diseased side before an attempt is made to remove the mass, and in ligaturing the inferior thyroid the position of the recurrent laryngeal nerve must be borne in mind, so as not to include it in the ligature.

A cystic or solid tumor of the thyroid may be removed by *intraglandular enucleation*. If operation becomes necessary in exophthalmic goitre, partial extirpation is usually preferred. Bilateral extirpation of the cervical ganglia of the sympathetic (*sympathectomy* or *Jonnesco's operation*) has been practised by some surgeons for exophthalmic goitre. The value of the procedure is uncertain.

FIG. 999.—The position of the parathyroid glands. View from behind. (Zuckerkandl.)

Parathyroids (Fig. 999).—If the thyroid gland has been carefully detached, two round bodies of small size may be found embedded upon the trachea or upon the surface of the lateral lobe of the gland, between the terminal branches of the inferior thyroid artery. "These are the parathyroids, about the size of orange-seeds, and brownish-red in color."[1] These masses are constant in man and are more distinct in infants than in adults. Although the parathyroids lie on or in the thyroid, they are always completely separated from it by capsules of connective tissue. The parathyroids are divided from their situation into **external** and **internal**. The former, usually two in number, are situated, one on each side, in relation to the postero-internal surface of the lateral lobe; sometimes they are duplicated. The latter, also usually two in number, are placed one in or on each lateral lobe, generally near its mesial surface.

Structure.—The structure of the parathyroids is different from that of the thyroid. They are composed of solid masses of epithelial cells arranged in a more or less columnar fashion with numerous intervening capillaries. The columns of the para-

[1] Practical Anatomy. By Prof. Alfred W. Hughes.

thyroids anastomose. There is much lymphoid tissue connected with the columns. Some regard the parathyroids as embryonic portions of the thyroid. This view seems to gain probability from the statement that after complete thyroidectomy, the parathyroids having been left, these structures increase in size, and apparently prevent operative myxœdema. If they are also removed, myxœdema arises. Nevertheless, MacCallum says "there is no histological proof that parathyroid tissue can ever become converted into thyroid tissue." Most observers regard the parathyroids as distinct glands possessed of a special function. Certain it is, as Gley and others have shown, removal of the parathyroids from herbivora leaving the thyroid intact is followed by spasms, tetany, etc., just as complete thyroidectomy is followed by such symptoms in carnivora.[1]

THE THYMUS GLAND (Fig. 1000).

The thymus gland is a temporary organ, attaining its full size at the end of the second year, when it ceases to grow and remains practically stationary until puberty, at which period it rapidly degenerates. It does not entirely disappear, for the shrunken and degenerated mass, even later in life, maintains a likeness to the original form and retains within its substance small portions of thymus tissue (Waldeyer). If examined when its growth is most active, it will be found to con-

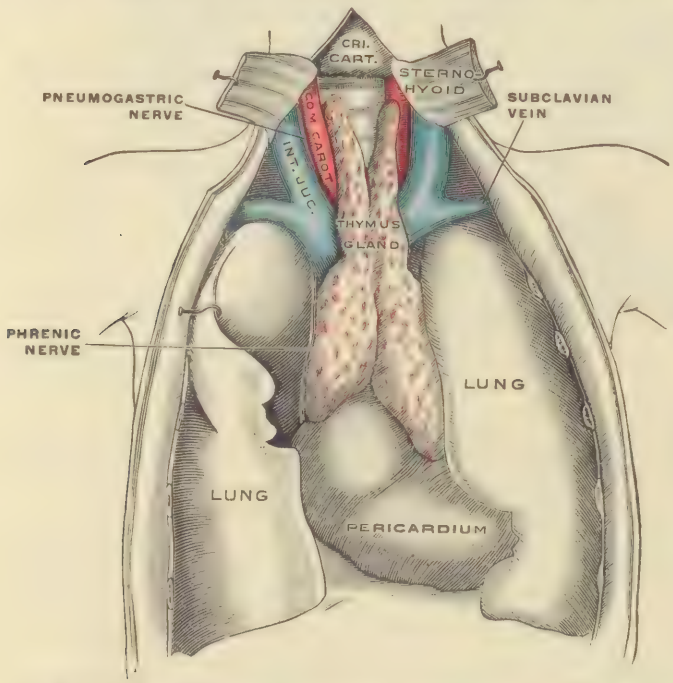

FIG. 1000.—The thymus gland in an infant two months old. (Poirier and Charpy.)

sist of two lateral lobes placed in close contact along the middle line, situated partly in the superior mediastinum, partly in the neck, and extending from the level of the fourth costal cartilage upward as high as the lower border of the thyroid gland. It is covered by the sternum and by the origins of the Sterno-hyoid and Sterno-thyroid muscles. Below, it rests upon the pericardium, being

[1] Internal Secretions. By William Hanna Thomson. New York Medical Journal, November 19, 1904.

separated from the arch of the aorta and great vessels by a layer of fascia. In the neck it lies on the front and sides of the trachea, behind the Sterno-hyoid and Sterno-thyroid muscles. The two lobes generally differ in size; they are occasionally united so as to form a single mass, and are sometimes separated by an intermediate lobe. The thymus is of a pinkish-gray color, is soft and is lobulated on its surfaces. It is about two inches in length, one and a half inches in breadth below, and about three or four lines in thickness. At birth it weighs about half an ounce.

Structure (Figs. 1001 and 1002).—Each lateral lobe is composed of numerous lobules held together by delicate areolar tissue, the entire gland being enclosed in an investing capsule of a similar but denser structure. The primary lobules vary in size from a pin's head to a small pea, and are made up of a number of small nodules or follicles which are irregular in shape and are more or less fused together, especially toward the interior of the gland. Each follicle consists of a medullary and cortical portion, which differ in many essential particulars from each other. The **cortical portion** is mainly composed of lymphoid cells supported by a delicate reticulum. In addition to this reticulum, of which traces only are found in the medullary portion, there is also a network of finely branched cells which is continuous with a similar network in the medullary portion. This network forms an adventitia to the blood-vessels. In the **medullary portion** there are but few lymphoid cells, but there are, especially toward the centre, granular cells and concentric corpuscles. The granular cells are rounded or flask-shaped masses attached (often by fibrillated extremities) to blood-vessels and to newly formed connective tissue. The concentric corpuscles are composed of a central mass consisting of one or more granular cells, and of a capsule which is formed of epithelioid cells which are continuous with the branched cells forming the network mentioned above.

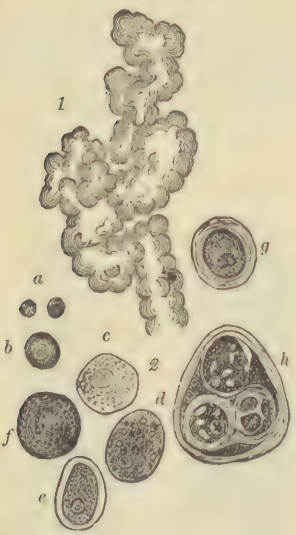

FIG. 1001.—Minute structure of thymus gland. Upper portion of the thymus of a fœtal pig of 2″ in length, showing the bud-like lobuli and glandular elements. 2, cells of the thymus, mostly from a man; *a*, free nuclei; *b*, small cells; *c*, larger; *d*, larger, with oil-globules, from the ox; *e*, *f*, cells completely filled with fat, at *f* without a nucleus; *g*, *h*, concentric bodies; *g*, an encapsulated nucleated cell; *h*, a composite structure of a similar nature.

Each follicle is surrounded by a capillary plexus from which vessels pass into the interior and radiate from the periphery toward the centre, and form a second zone just within the margin of the medullary portion. In the centre of the medulla there are very few vessels, and they are of minute size.

Watney has made the important observation that hæmoglobin is found in the thymus either in cysts or in cells situated near to or forming part of the concentric corpuscles. This hæmoglobin varies from granules to masses exactly resembling colored blood-corpuscles, oval in the bird, reptile, and fish; circular in all mammals except in the camel. Dr. Watney has also discovered in the lymph issuing from the thymus similar cells to those found in the gland, and, like them, containing hæmoglobin either in the form of granules or masses. From these facts he arrives at the physiological conclusion that the thymus is one source of the colored blood-corpuscles.

Vessels and Nerves.—The **arteries** supplying the thymus are derived from the **internal mammary** and from the **superior** and **inferior thyroid**. The **veins** terminate in the two **innominate veins**, and in the **internal mammary** and the **thyroid veins**. The **lymphatics** are of large size, arise in the substance of the gland, and are said to terminate in the **internal jugular vein**. The **nerves** are

exceedingly minute; they are derived from the **pneumogastric** and **sympathetic**. Branches from the **descendens hypoglossi** and **phrenic** reach the investing capsule, but do not penetrate into the substance of the gland.

FIG. 1002.—Minute structure of the thymus gland. Follicle of injected thymus from a calf, four days old, slightly diagrammatic, magnified about 50 diameters. The large vessels are disposed in two rings, one of which surrounds the follicle, the other lies just within the margin of the medulla. *A* and *B*, from thymus of camel, examined without addition of any reagent. Magnified about 400 diameters. *A*, large colorless cell containing small oval masses of hæmoglobin. Similar cells are found in the lymph-glands, spleen, and medulla of bone; *B*, colored blood-corpuscles. (Watney.)

THE CAROTID GLAND OR CAROTID BODY (GLOMUS CAROTICUM).

This body, when present, lies in the carotid bifurcation, to the inner side of the common carotid below the bifurcation, or on the posterior surface of the internal or of the external carotid. It is often absent. It lies in fatty tissue and is surrounded by a fibrous capsule which is attached to the carotid sheath. The carotid gland is about the size of a grain of corn; it is oval in shape and reddish-brown in color. The capsule of the gland sends septa inward. The septa divide the organ into follicles or **cell-balls**. These cell-balls are composed of endothelial cells and are associated with blood capillaries. A branch (or branches) from the **carotid artery** enters the carotid gland, and the gland is closely connected with the **carotid plexus of the sympathetic.** (This structure has been recently studied by John Funke,[1] Reclus and Chevasson,[2] Paltauf, Kartschenko, and Marchand.)

Surgical Anatomy.—*Tumors* may arise from this structure. Such a tumor is apt to be above the level of the upper margin of the thyroid cartilage and in most cases it moves with each arterial beat.

[1] American Medicine, vol. viii., No. 3.

[2] Bull. et mém. de la Soc. de chir. de Paris, 1903, No. 18.

THE COCCYGEAL GLAND OR COCCYGEAL BODY OR LUSCHKA'S GLAND (GLOMUS COCCYGEUM).

Lying near the tip of the coccyx in a small tendinous interval formed by the union of the Levator ani muscles and just above the coccygeal attachment of the Sphincter ani, is a small conglobate body about as large as a lentil or a pea, first described by Luschka,[1] and named by him the coccygeal gland. Its most obvious connections are with the arteries of the part. It is similar in structure to the carotid body.

Structure.—It consists of a congeries of small arteries with little aneurismal dilatations derived from the middle sacral and freely communicating with each other. These vessels are enclosed in one or more layers of polyhedral granular cells, and the whole structure is invested in a capsule of connective tissue which sends in trabeculae, dividing the interior into a number of spaces in which the vessels and cells are contained. Nerves pass into this little body from the sympathetic, but their mode of termination is unknown. Macalister believes the glomerulus of vessels "consists of the condensed and convoluted metameric dorsal arteries of the caudal segments embedded in tissue which is possibly a small persisting fragment of the neurenteric canal." It resembles the carotid gland in structure, and is probably one of the ductless glands.

THE URINARY ORGANS.

THE KIDNEYS (RENES) (Figs. 1003, 1004, 1005).

THE Kidneys are large glands. They are two in number, and are situated in the back part of the abdomen, near the spinal column. Their function is to separate from the blood certain materials which, when dissolved in a quantity of water, also separated from the blood by the kidneys, constitute the **urine**.

They are placed in the loins, one on each side of the vertebral column, behind the peritoneum, and are surrounded by a mass of fat and loose areolar tissue, which

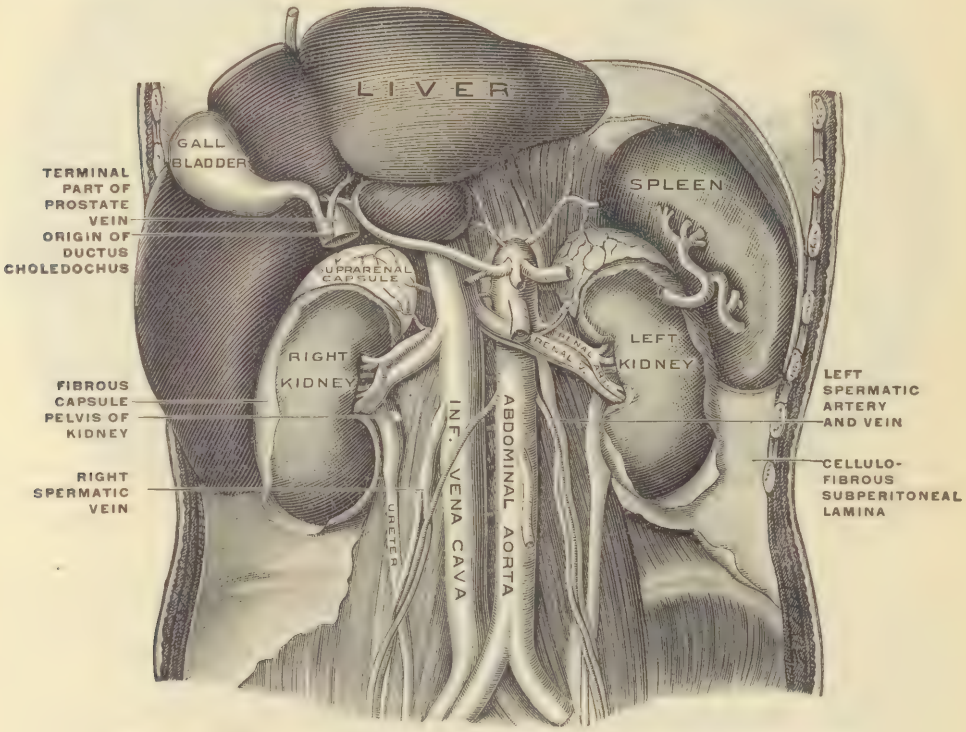

FIG. 1003.—The situation, direction, forms, and supports of the kidney. (Sappey.)

constitutes the **fatty capsule** (*capsula adiposa*) (Figs. 1008 and 1009). There are two distinct layers in this fatty capsule. The superficial fatty layer is the **pararenal fat.**[1] Keen calls this layer the **transversalis layer of fat,** because it is derived from the transversalis fascia.[2] The deeper and thicker perirenal layer is the **true perinephric fat** (Fig. 1009). The deeper layer of fat completely surrounds the kidney, and is somewhat adherent to the fibrous renal capsule. The fat about the kidney does

[1] See Gerota, Arch. f. Anatomie, Leipzic, 1895; Zuckerkandl, Medizinische Jahrbücher, Vienna, 1883.
[2] W. W. Keen, in American Medicine, January 31, 1903.

not look like fat in other regions, but is soft, delicate, and of a canary yellow color. These two layers are separated by a layer of connective tissue, which is the **posterior layer of the perirenal fascia,** and is called by Zuckerkandl the **retro-renal fascia** (*fascia retrorenalis*) (Fig. 1008). The **true capsule of the kidney** (*tunica fibrosa*) is thin, smooth, and glistening. The inner part of this capsule (*tunica muscularis*) contains unstriated muscle fibres. The true capsule can be easily separated from the underlying glandular structure. The upper extremity of the kidney is on a level with the upper border of the twelfth dorsal vertebra, the lower extremity on a level with the third lumbar vertebra (Fig. 1006). The right kidney is usually on a slightly lower level than the left, probably on account of the vicinity of the liver. In the female the kidneys are a little lower than in the male.

Each kidney is about four and a half inches in length, two to two and a half in breadth, and rather more than one inch in thickness. The left is somewhat longer, though narrower, than the right. The weight of the kidney in the adult male varies from 4½ ounces to 6 ounces; in the adult female, from 4 ounces to 5½ ounces. The combined weight of the two kidneys in proportion to the body is about 1 in 240.

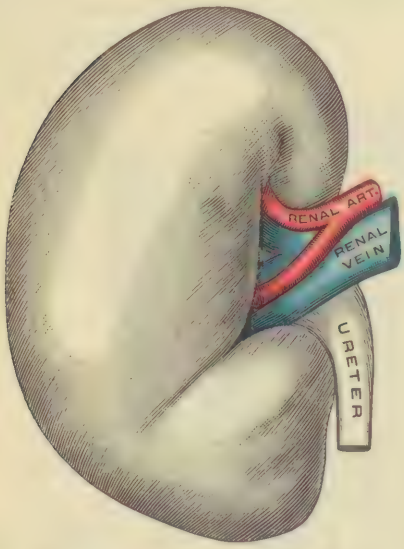

FIG. 1004.—Anterior surface of the kidney. (Bourgery.)

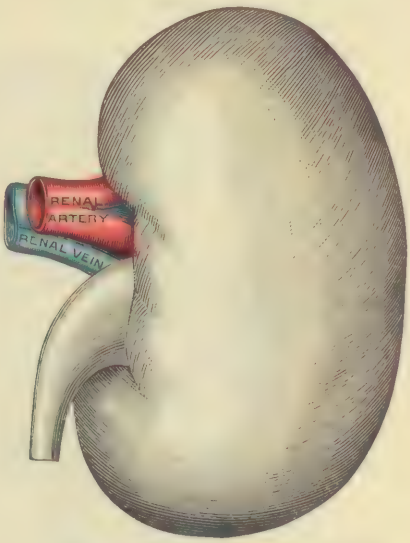

FIG. 1005.—Posterior surface of the kidney. (Bourgery.)

The kidney has the characteristic form of a "flattened bean" (Spalteholz). It is flattened on its sides and presents at one part of its circumference a hollow. It is larger at its upper than at its lower extremity. The kidney presents for examination two **surfaces,** two **borders,** and an **upper** and **lower extremity.**

Surfaces. The Anterior Surface (*facies anterior*) (Figs. 1003 and 1004).—Its anterior surface is convex, looks forward and outward, and is partially covered by peritoneum. The right kidney in its upper three-fourths is in contact with the posterior part of the under surface of the right lobe of the liver. This area of the right kidney is flattened (*impressio hepatica*). Toward its inner border it is covered by the second part of the duodenum, while its lower and outer part is in relation with the hepatic flexure of the colon. The relation of the second part of the duodenum to the front of the right kidney is a varying one. The left kidney is covered above by the posterior surface of the stomach, below the stomach by the pancreas, behind which are the splenic vessels. The region in contact with the stomach is markedly depressed (*impressio gastrica*). Its lower half is in contact with some of the coils

of the small intestine and sometimes with the third part of the duodenum. Near its outer border the anterior surface lies behind the spleen and the splenic flexure of the colon.

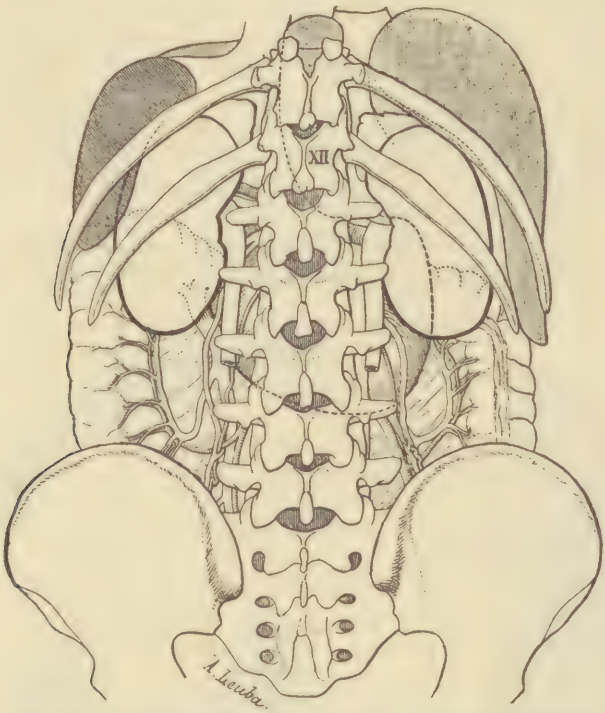

FIG. 1006.—Posterior surface of the kidneys. (Poirier and Charpy.)

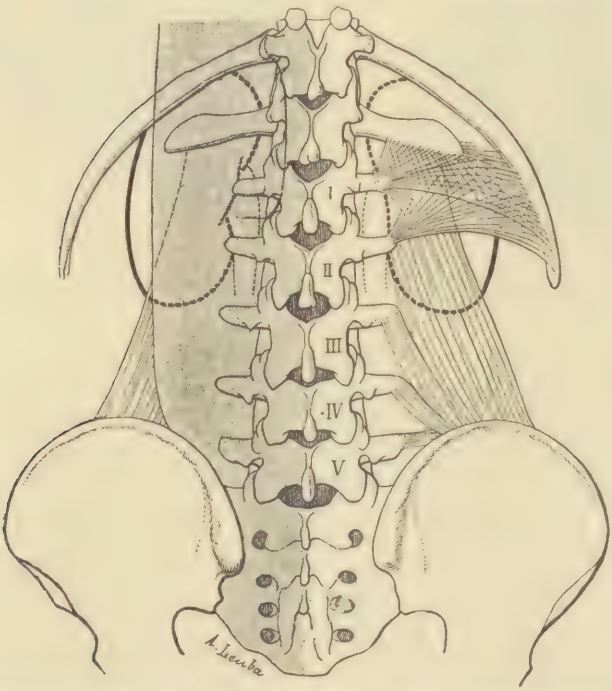

FIG. 1007.—Relation of the kidney to the vertebral column, ribs, muscles, and lumbo-costal ligaments. (Poirier and Charpy.)

The kidneys are partly covered in front by peritoneum and partly uncovered. On the right kidney, the **hepatic area**, that is to say that portion of the kidney which produces the renal impression on the liver, is covered by peritoneum, which therefore separates the kidney from the liver; the **duodenal** and **colic areas** are not peritoneal, and these structures are connected to the kidney by loose connective tissue; at the lower and inner extremity is a small area, the **mesocolic area**, which is covered by a layer of peritoneum of the greater sac and by the colic vessels. On the left kidney the **gastric area** is covered by the peritoneum of the lesser sac; the **pancreatic** and **colic areas** are non-peritoneal; while, as on the right side, at the lower and inner extremity, is an area, **mesocolic area**, which is covered by the peritoneum of the greater sac and by the colic vessels.

The Posterior Surface (*facies posterior*) (Fig. 1005).—The posterior surface of the kidney is flatter than the anterior and is directed backward and inward. It is

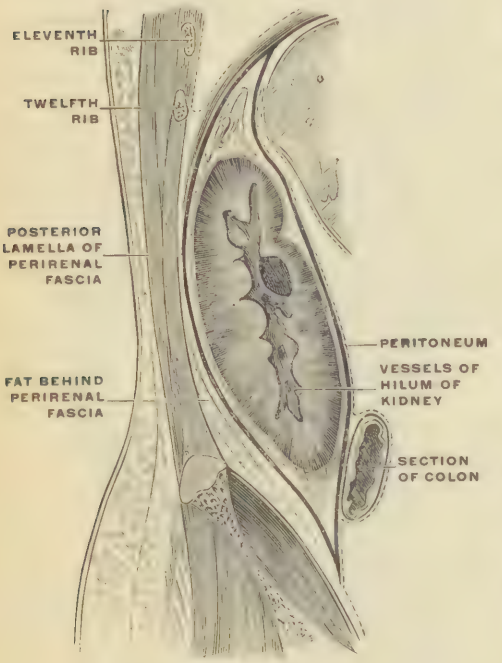

Fig. 1008.—Longitudinal section, showing the arrangement of the capsule of the kidney. (After Gerota.)

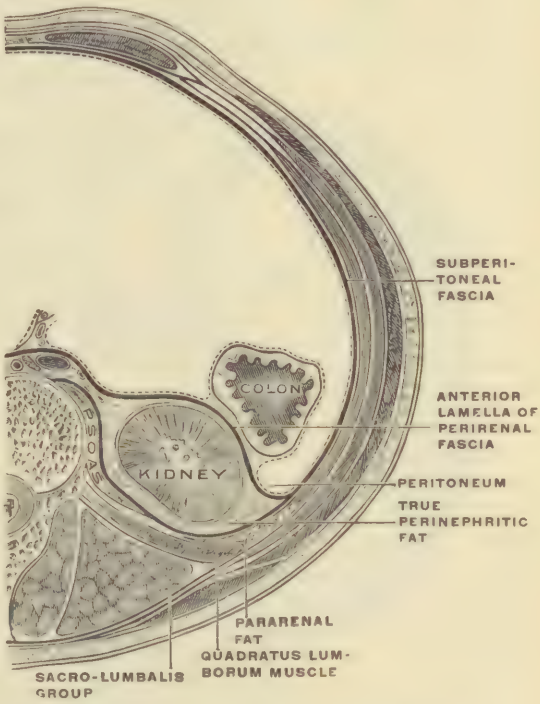

Fig. 1009.—Transverse section, showing the relations of the capsule of the kidney and the two layers of fat. (After Gerota.)

entirely devoid of peritoneal covering, being embedded in areolar and fatty tissue. It lies upon the Diaphragm, the anterior layer of the lumbar aponeurosis, the external and internal arcuate ligaments, the Psoas and Transversalis muscles, one or two of the upper lumbar arteries, the last dorsal, ilio-hypogastric, and ilio-inguinal nerves. The **lumbo-costal ligaments** overlie the posterior surface of the kidney (Fig. 1007). The right kidney rests upon the twelfth rib (Fig. 1007), the left usually on the eleventh and twelfth ribs. The Diaphragm separates the kidney from the pleura as the pleura dips down to form the **phrenico-costal sinus** (Fig. 987), but frequently the muscular fibres of the Diaphragm are defective or absent over a triangular area immediately above the external arcuate ligament, and when this is the case the perirenal areolar tissue is in immediate apposition with the diaphragmatic pleura. In the lower part of the posterior surface of the kidney is an impression produced by the Quadratus lumborum muscle and called

the **impressio muscularis**. A little internal to this a flattening, caused by the Psoas muscle, is often recognizable. At the upper part of the posterior surface is a sulcus produced by contact with the Diaphragm.

Borders. **The External Border** (*margo lateralis*) (Figs. 1004 and 1005).—The external border is convex, and is directed outward and backward, toward the postero-lateral wall of the abdomen. On the left side it is in contact, at its upper part, with the spleen (Fig. 1003).

The Internal Border (*margo medialis*) (Figs. 1004 and 1005).—The internal border is concave, and is directed forward, inward, and a little downward. It presents a deep longitudinal fissure, bounded by a prominent overhanging anterior and posterior lip. This fissure is named the **hilum** (*hilus renalis*) (Fig. 1010), and allows of the passage of the vessels, nerves, and ureter into and out of the kidney.

Extremities. **The Superior Extremity** (*extremitas superior*) (Figs. 1004 and 1005.—The superior extremity, directly slightly inward as well as upward, is thick and rounded, and is surmounted by the suprarenal capsule (Fig. 1010), which covers also a small portion of the anterior surface.

The Inferior Extremity (*extremitas inferior*) (Figs. 1004 and 1005).—The inferior extremity, directed a little outward as well as downward, is smaller and thinner than the superior. It extends to within two inches of the crest of the ilium.

At the hilum of the kidney the relative position of the main structures passing into and out of the kidney is as follows: the vein is in front, the artery in the middle, and the duct or ureter behind and toward the lower part (Fig. 1005). By a knowledge of these relations the student may distinguish between the right and left kidney. The kidney is to be laid on the table before the student on its posterior surface, with its lower extremity toward the observer—that is to say, with the ureter *behind* and *below* the other vessels; the hilum will then be directed to the side to which the kidney belongs.

General Structure of the Kidney.—The kidney is surrounded by a distinct investment of fibrous tissue (*tunica fibrosa*), which forms the firm, smooth, **true capsule** covering the entire organ. The capsule passes over the margins of the hilum, enters the interior of the kidney, and covers the wall of the sinus. The true capsule is closely and firmly adherent to the renal pelvis where it is attached to the sinus. It closely invests it, but can be easily stripped off, in doing which, however, numerous fine processes of connective tissue which pass to the intrarenal connective tissue and numerous small blood-vessels are torn through. Beneath this fibrous layer a thin wide-meshed network of unstriped muscular fibre forms an incomplete covering to the organ. When the true capsule is stripped off, the surface of the kidney is found to be smooth, even, and of a deep-red color.

In infants fissures extending for some depth may be seen on the surface of the organ, a remnant of the lobular construction of the gland (Fig. 1027). The kidney is dense in texture, but is easily lacerable by mechanical force. In order to obtain a knowledge of the structure of the gland, a vertical section must be made from its convex to its concave border, and the loose tissue and fat removed around the vessels and the excretory duct (Fig. 1010). It will be then seen that the kidney consists of a central cavity surrounded at all parts but one by the proper kidney-substance. This central cavity is called the **sinus** (*sinus renalis*), and is lined by a prolongation of the fibrous coat of the kidney, which enters through a longitudinal fissure, the **hilum** (*hilus renalis*) (Fig. 1010), which is situated at that part of the cavity which is not surrounded by kidney structure. Through this fissure the blood-vessels of the kidney and its excretory duct pass, and therefore these structures, upon entering the kidney, are contained within the sinus (Fig. 1004). The **excretory duct** or **ureter**, after entering, dilates into a wide, funnel-shaped sac named the **pelvis** (*pelvis renalis*) (Figs. 1010 and 1011). This divides into two or three tubular divisions, which subdivide into several short,

truncated branches named **calices** or **infundibula** (*calyces renales*), all of which are contained in the central cavity of the kidney (Figs. 1010 and 1011). The blood-vessels of the kidney, after passing through the hilum, are contained in the sinus or central cavity, lying between its lining membrane and the excretory apparatus, before entering the kidney-substance (Fig. 1011).

This central cavity, as before mentioned, is surrounded on all sides except at the hilum by the substance of the kidney, which is at once seen to consist of two parts—viz., of an external granular investing part, which is called the **cortical portion** (*substantia corticalis*); and of an internal part, the **medullary portion** (*substantia medullaris*), made up of a number of dark-colored **pyramids,** with their bases resting on the cortical part and their apices converging toward the centre, where they form prominent papillae, the **renal papillae** (*papillae renales*), which project into the interior of the calices (Fig. 1010).

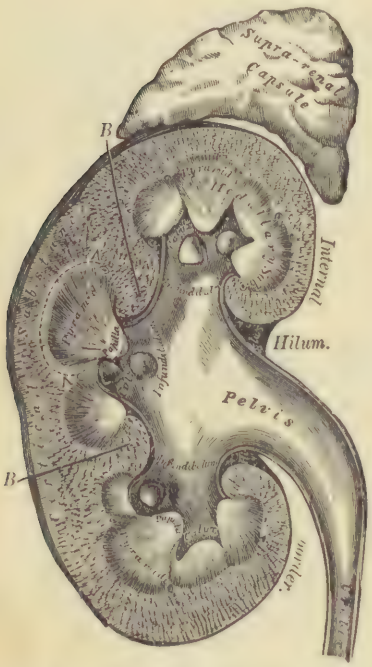

Fig. 1010.—Vertical section of kidney.

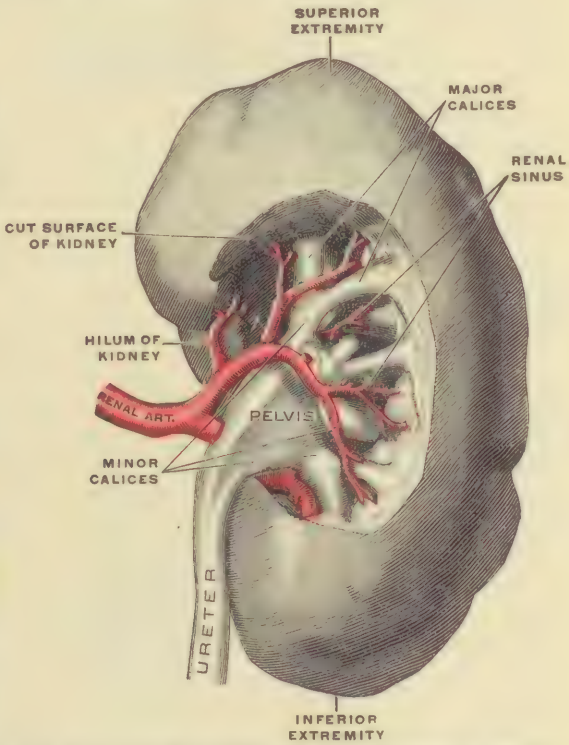

Fig. 1011.—The right kidney with its pelvis exposed, viewed from behind. (Spalteholz.)

The **cortical substance** (Figs. 1010 and 1017) is of a bright reddish-brown color, soft, granular, and easily lacerable. It is found everywhere immediately beneath the capsule, and is seen to extend in an arched form over the base of each medullary pyramid. Prolongations of the cortical substance pass between the pyramids toward the renal sinus. These prolongations are the **cortical columns** or the **columns of Bertin** (*columnae renales*) (Fig. 1010, *B B*). The columns contain blood-vessels, nerves, and lymphatics. The base of each pyramid (*basis pyramidis*) is known as the **intermediate zone.** That portion of the cortical substance which stretches from one cortical column to the next, and intervenes between the base of the pyramid and the capsule (marked by the dotted line extending from *A* to *A'* in Fig. 1010), is called a **cortical arch,** the depth of which varies from a third to half an inch.

The **medullary substance** (Figs. 1010 and 1017), as before stated, is seen to consist of red-colored, striated, conical masses, the **pyramids of Malpighi** (*pyramides*

renales) (Fig. 1010), the number of which, varying from eight to eighteen, corresponds to the number of lobes of which the organ in the fœtal state is composed. The pyramids are composed of straight tubes which pass between the apices of the papillae and the cortical margin. They enter the cortex in masses called the **pyramids of Ferrein** (see below). The sides of the pyramids of Malpighi are contiguous with the cortical columns, while the apices, known as the **papillae of the kidney** (*papillae renales*) (Figs. 1010 and 1014), project into the calices of the ureter, each calyx receiving two or three papillae. Radiating from the bases of the pyramids of Malpighi are ridges of cortical substance with distinct depressions between them. These ridges are the **medullary rays** (*pars radiata*) or **pyramids of Ferrein** (Figs. 1013 and 1017). The **labyrinth of the cortex** (Fig. 1013) is constituted by the kidney substance between the rays. The pyramids of Ferrein look like direct continuations of the medullary substance, but, in reality, they are in the cortex, and are formed by the straight tubes extending in masses into the cortex. The pyramids of Ferrein are much smaller than the pyramids of Malpighi. In the columns of Bertin blood-vessels, nerves, and lymphatics pass to and emerge from the sinus by way of small foramina. The summit of a papilla contains a number of orifices of papillary ducts. Such an area is called an **area cribrosa** (Fig. 1014).

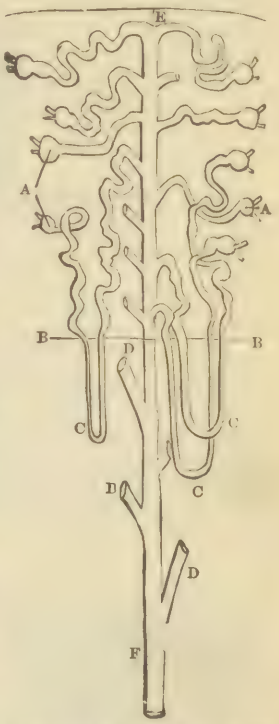

FIG. 1012.—Plan of uriniferous tubes. *A A*, Malpighian bodies; *B B*, margin of medullary structure; *C, C, C*, loops of Henle; *D, D, D*, straight tubes cut off; *E*, commencing straight tubes; *F*, termination of straight tube or the excretory tube.

These two parts, *cortical* and *medullary*, so dissimilar in appearance, are very similar in structure, being made up of urinary tubes and blood-vessels united and bound together by a connecting matrix or stroma.

Minute Anatomy.—The **uriniferous tubes, urinary canals** or **tubuli uriniferi** (*tubuli renales*) (Figs. 1012 and 1017), of which the kidney is for the most part made up, commence in the cortical portion of the kidney. Each tubule begins between the medullary rays (Fig. 1013) in a sac, Bowman's capsule or the Malpighian capsule (see below). The tubules, as a rule, after pursuing a very circuitous course through the cortical and medullary parts of the kidney, finally terminate at the apices of the Malpighian pyramids by open mouths, so that the fluid which they contain is emptied into the dilated extremity of the ureter contained in the sinus of the kidney. If the surface of one of the papillae is examined with a lens, it will be seen to be studded over with a number of small depressions (*foramina papillaria*), from sixteen to twenty in number, and in a fresh kidney, upon pressure being made, fluid will be seen to exude from these depressions. They are the orifices of the tubuli uriniferi, which terminate in this situation. The tubuli uriniferi begin in the cortex as the **Malpighian bodies** or **corpuscles** (*corpuscula renis*) (Figs. 1012, 1013, 1015, 1016, and 1018), which are small rounded masses, varying in size, but average about $\frac{1}{120}$ of an inch in diameter. They are of a deep-red color, and are found only in the cortical portion of the kidney. Each of these little bodies is composed of two parts—a central glomerulus of vessels, called a **Malpighian tuft**, and a membranous envelope, the **Malpighian capsule** or **capsule of Bowman** (*capsula glomeruli*), which latter is a small pouch-like commencement of a uriniferous tubule.

The **Malpighian Tuft** or **Vascular Glomerulus** (Figs. 1015, 1016, 1017, 1022, and 1023) is a network of convoluted capillary blood-vessels held together by scanty

connective tissue and grouped into from two to five lobules. This capillary network is derived from a small arterial twig, the **afferent vessel**, which pierces the wall of the capsule, generally at a point opposite that at which the latter is connected with the tube; and the resulting **efferent vessel** emerges from the capsule at the same

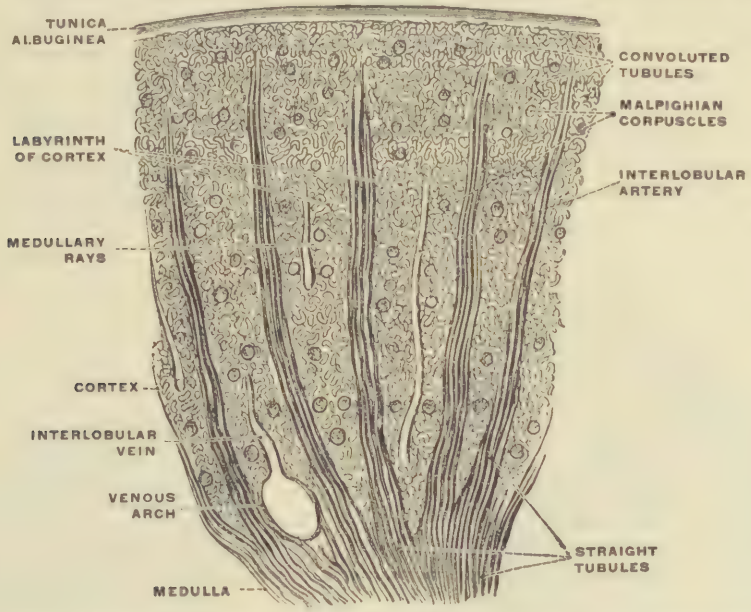

FIG. 1013.—Part of a section through the cortex of the kidney in the direction of the straight tubules. (Toldt.)

point. The afferent vessel is usually the larger of the two (Fig. 1015). The **Malpighian** or **Bowman's capsule** (*capsula glomeruli*) (Figs. 1015, 1016, and 1017), which surrounds the glomerulus, is formed of a hyaline membrane supported by a small amount of connective tissue which is continuous with the connective tissue of the tube. It is lined on its inner surface with a layer of squamous epithelial cells which are reflected from the lining membrane on to the glomerulus at the point of entrance or exit of the afferent and efferent vessels. The whole surface of the glomerulus is covered with a continuous layer of the same cells on a delicate supporting membrane, which with the cells dips in between the lobules of the glomerulus, closely surrounding them (Fig. 1016). Thus, between the glomerulus and the capsule a space is left, forming a cavity lined by a continuous layer of cells, which varies in size according to the state of secretion and the amount of fluid present in it. The cells, as above stated, are squamous in the adult, but in the fœtus and young subject they are polyhedral or even columnar.

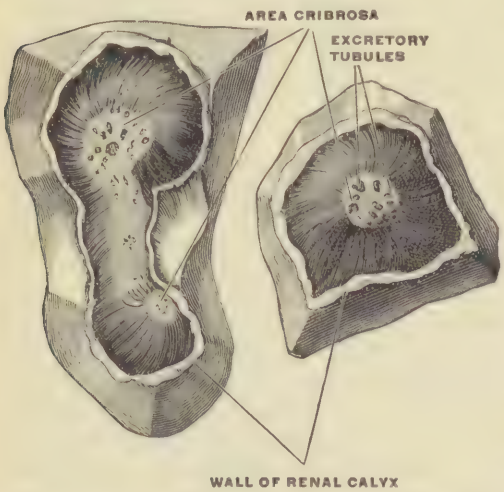

FIG. 1014.—Area cribrosa of renal papilla. (Toldt.)

The **Tubuli Uriniferi**, commencing in the Malpighian bodies, in their course present many changes in shape and direction (*tubuli renales contorti*), and are

contained partly in the medullary and partly in the cortical portions of the organ. At the junction of a tubule with the Malpighian capsule there is a somewhat constricted portion which is termed the **neck** (Fig. 1018). Beyond this the tubule becomes convoluted, and pursues a considerable course in the cortical structure, constituting the **proximal** or **first convoluted tubule** (Figs. 1017 and 1018). After a time the convolutions disappear, and the tubule approaches the medullary portion of the kidney in a more or less spiral manner. This section of the tubule has been called the **spiral tube of Schachowa** (Fig. 1018). Throughout this portion of their course the tubuli uriniferi have been contained entirely in the cortical structure, and have presented a pretty uniform calibre. They now enter the medullary portion, and suddenly become much smaller, quite straight in direction (*tubuli renales recti*), and each tubule dips down for a variable depth into the pyramids, constituting the **descending limb of Henle's loop** (Figs. 1017 and 1018). Bending on itself, it forms a kind of loop near the apex of the pyramid, the **loop of Henle,** and, reascending, becomes suddenly enlarged and again spiral in direction, forming the **ascending limb of Henle's loop** (Figs. 1017 and 1018),

FIG. 1015.—Minute structure of kidney.

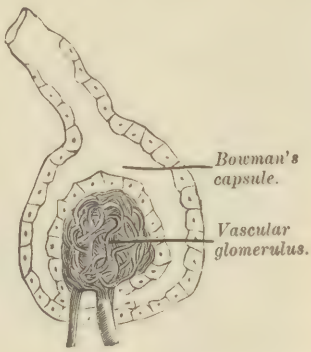

FIG. 1016.—Malpighian body.

and re-enters the cortical structure. This portion of the tubule does not present a uniform calibre, but becomes narrower as it ascends and irregular or somewhat spiral in outline (Fig. 1018). As a narrow tube it enters the cortex and ascends for a short distance, when it again becomes dilated, irregular, and angular. This section is termed the **irregular tubule** (Fig. 1018); it terminates in a convoluted tubule which exactly resembles the proximal convoluted tubule; and is called the **distal** or **second convoluted tubule** (Figs. 1017 and 1018). This again terminates in a narrow **curved** or **junctional tubule**, which enters the straight or collecting tube.

Each **straight collecting** or **receiving tube** (Figs. 1012, 1017, and 1018) commences by a small orifice on the summit of a papilla, thus opening and discharging its contents into the interior of one of the calices. Traced into the substance of the pyramid, these tubes are found to run from apex to base, dividing dichotomously in their course and slightly diverging from each other. Thus dividing and subdividing, they reach the base of the pyramid, and enter the cortical structure greatly increased in number. Upon entering the cortical portion they continue a straight course for a variable distance, and are arranged in groups, several of these groups corresponding to a single pyramid. The tubes in the centre of the group are the longest, and reach almost to the surface of the kidney, while the external ones are shorter, and advance only a short distance into the cortex. In consequence of this arrangement the cortical portion presents a number of conical masses, the apices of which reach the periphery of the organ,

and the bases are applied to the medullary portion. These are termed the **medullary rays** or the **pyramids of Ferrein** (Fig. 1013; also p. 1417). As they run through the cortical portion the straight tubes receive on either side the curved extremity of the convoluted tubes, which, as stated above, commence at the Malpighian bodies. Each collecting tube receives a number of tubules, and several collecting tubes unite together to form a **papillary duct** (Fig. 1017) and open by a foramen (Fig. 1014) at the surface of the papilla.

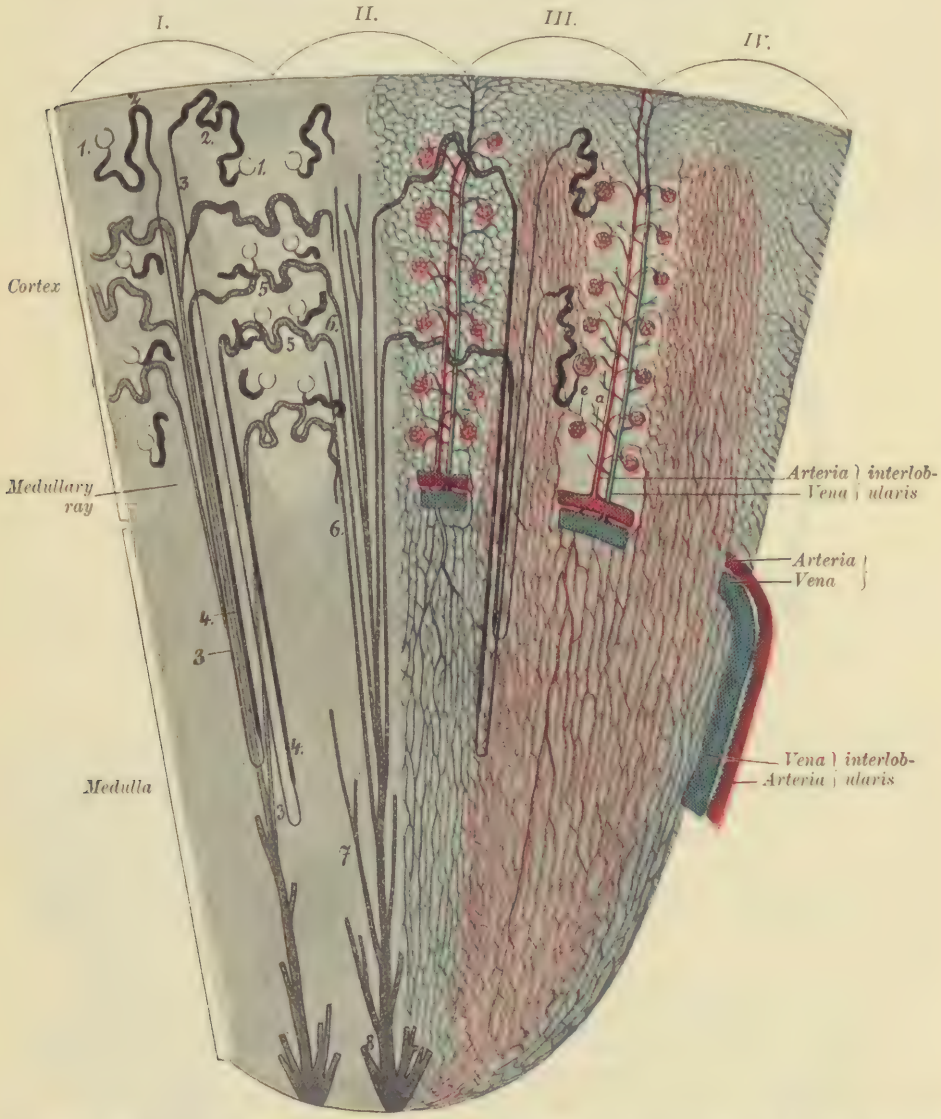

FIG. 1017.—Diagrammatic representation of the course of the urinary canals (left) and the kidney vessels (right). The arteries are red, the veins blue; capsules of Bowman, convoluted tubules I. order and loops of Henle are black; convoluted tubules II. order and collecting tubules gray. I., II., III., IV., four kidney lobules; *a*, vas afferens; *e*, vas efferens. 1, Bowman's capsule; 2, convoluted tubule I. order; 3, descending limb of loop of Henle; 4, ascending limb of loop of Henle; 5, convoluted tubule II. order; 6, 7, collecting tubules; 8, papillary duct. (Szymonowicz.)

It will be seen from the above description that there is a continuous series of tubes from their commencement in the Malpighian bodies to their termination at the orifices on the apices of the pyramids of Malpighi, and that the urine,

the secretion of which commences in the capsule, finds its way through these tubes into the calices of the kidney, and so into the ureter. To recapitulate: the tube first presents a constricted portion, (1) the **neck.** 2. It forms a wide convoluted tube, the **proximal convoluted tube.** 3. It becomes spiral, the **spiral tubule of Schachowa.** 4. It enters the medullary structure as a narrow, straight tube, the **descending limb of Henle's loop.** 5. Forming a loop and becoming dilated, it ascends somewhat spirally, and, gradually diminishing in calibre, again enters the cortical structure, the **ascending limb of Henle's loop.** 6. It now becomes irregular and angular in outline, the **irregular tubule.** 7. It then becomes convoluted, the **distal convoluted tubule.** 8. Diminishing in size, it forms a curve, the **curved** or **junctional tubule.** 9. Finally, it joins a straight tube, the **straight collecting tube,** which is continued downward through the medullary substance and joins other straight tubes to form a **papillary duct,** which opens in a foramen at the apex of a pyramid.

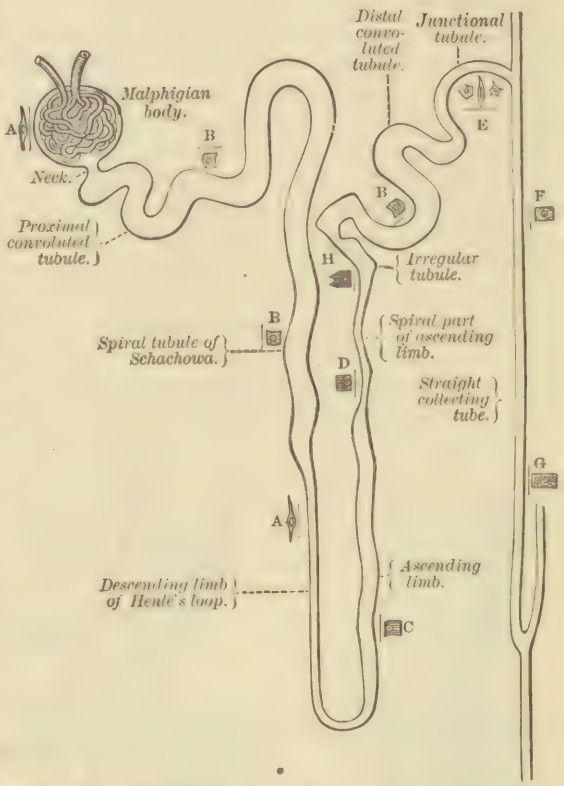

FIG. 1018.—Uriniferous tube. For the sake of clearness the epithelial cells have been represented more highly magnified than the tubes in which they are contained.

THE TUBULI URINIFERI: THEIR STRUCTURE (Figs. 1019, 1020, and 1021.—The tubuli uriniferi consist of basement-membrane lined with epithelium. The

[1] From Handbook for the Physiological Laboratory.

epithelium varies considerably in different sections of the uriniferous tubes. In the neck the epithelium is continuous with that lining the Malpighian capsule, and, like it, consists of flattened cells with an oval nucleus (Fig. 1016). The cells are, however, very indistinct and difficult to trace, and the tube has here the appearance of a simple basement-membrane unlined with epithelium. In the proximal convoluted tubule and the spiral tubule of Schachowa the epithelium is polyhedral in shape, the sides of the cells not being straight, but fitting into each other, and in some animals so fused together that it is impossible to make out the lines of junction. In the human kidney the cells often present an angular projection of the surface next the basement-membrane. These cells are made up of more or less rod-like fibres, which rest by one extremity on the basement-membrane, whilst the other projects toward the lumen of the tube. This gives to the cells the appearance of distinct striation. In the descending limb of Henle's loop the epithelium resembles that found in the Malpighian capsule and the commencement of the tube, consisting of flat transparent epithelial plates with an oval nucleus (Fig. 1019). In the ascending limb, on the other hand, the cells partake more of the character of those described as existing in the proximal convoluted tubule, being polyhedral in shape and presenting the same appearance of striation. The nucleus, however, is not situated in the centre of the cell, but near the lumen (Fig. 1021). After the ascending limb of Henle's loop becomes narrower upon entering the cortical structure, the striation appears to be confined to the outer part of the cell; at all events, it is much more distinct in this situation, the nucleus, which appears flattened and angular, being still situated near the lumen. In the irregular tubule the cells undergo a still further change, becoming very angular, and presenting thick bright rods or markings, which render the striation much more distinct than in any other section of the urinary tubules. In the distal convoluted tubule the epithelium appears to be somewhat similar to that which has been described as existing in the proximal convoluted tubule, but presents a peculiar refractive appearance. In the curved tubule, just before its entrance into the straight collecting tube, the epithelium varies greatly as regards the shape of the cells, some being angular with short processes, others spindle-shaped, others polyhedral.

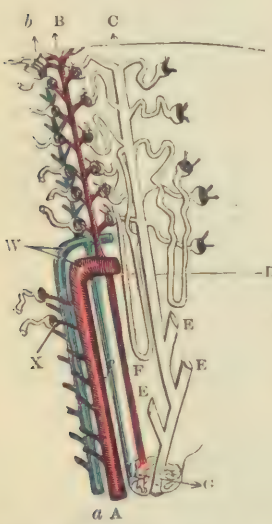

FIG. 1022.—Diagrammatic sketch of the blood-vessels of the kidney.

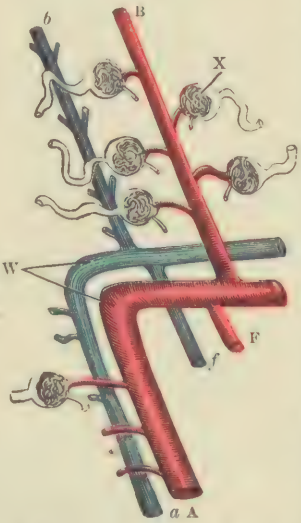

FIG. 1023.—A portion of Fig. 1022 enlarged. (The references are the same.)

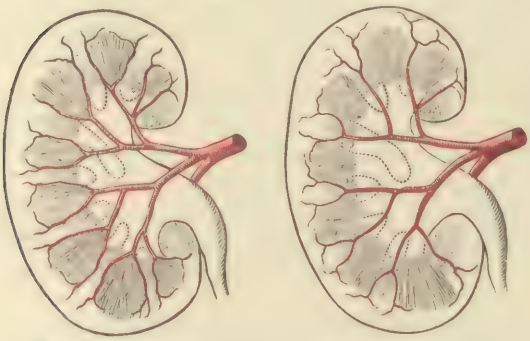
A, *a*, interlobar artery and vein, the former giving off the renal afferents, the latter receiving the renal efferents; B, *b*, interlobular artery and vein, the latter commencing from the stellate veins, and receiving branches from the plexus around the tubuli contorti, the former giving off renal afferents; C, straight tube, surrounded by tubuli contorti, with which it communicates, as more fully shown in Fig. 1023; D, margin of medullary substance; E, E, E, receiving tubes cut off; F, *f*, arteriolae et venae rectae, the latter arising from (G) the plexus at the medullary apex; X, vascular glomerulus; W, the arcuate artery and vein.

In the straight tubes the epithelium is more or less columnar; in its papillary portion the cells are distinctly columnar and transparent (Fig. 1020), but as the tube approaches the cortex the cells are less uniform in shape; some are polyhedral, and others angular with short processes.

The Renal Blood-vessels.—The kidney is plentifully supplied with blood by the renal artery (Figs. 422, 423, 1005, and 1011), a large offset of the abdominal aorta. Previously to entering the kidney, each artery divides into four or five branches, which are distributed to its substance. At the hilum these branches lie between the renal vein and ureter, the vein being in front, the ureter behind. Each vessel gives off a small branch to the suprarenal capsules, the ureter, and the surrounding cellular tissue and muscles. It has been pointed out by Hyrtl (p. 679) that the renal artery gives off a branch which divides and supplies the dorsal portion of the kidney and a branch which divides and supplies the ventral portion of the kidney (Figs. 422 and 423). Between these two vascular systems is a non-vascular zone, called by Byron Robinson the **exsanguinated renal zone of Hyrtl** (Figs. 422 and 423). It "is one-half inch dorsal to the lateral longitudinal renal border."[1] Frequently there is a second renal artery, which is given off from the abdominal aorta at a lower level, and supplies the lower portion of the kidney. It is termed the **inferior renal artery**. The branches of the renal arteries pass to the kidney substance between the pyramids and are known as **interlobar arteries** (*arteriae interlobares renis*) (Figs. 1013, 1017, 1024, and 1025). At the junction of the cortical and medullary portions these vessels turn and for a short distance pursue a course parallel to the kidney surface. There are thus formed a series of incomplete vascular arches across the bases of the pyramids, the **arcuate arteries** (*arteriae arciformes*) (Figs. 1017, 1022, and 1023). From these arches two sets of vessels come. The vessels of one set go to the periphery and enter the labyrinth, those of the other set pass toward the centre and enter the intermediate zone of the medulla. These last vessels are the *arteriolae recti* (Figs. 1017, 1022, and 1023). Because of these vessels the kidney exhibits striations on section. Each of the arteriolae recti in the medulla divides into numerous small branches which are nearly parallel to each other and supply the tubules of this region. The arteries which arise from the arches and pass to the periphery are the **interlobular arteries** (*arteriae interlobulares*) (Figs. 1017, 1022, 1023, and 1026). They traverse the labyrinth and pass toward the surface of the kidney. A number of short branches, the **vasa afferentia**, are given off by the interlobular arteries (Figs. 1017, 1022, 1023, and 1026). Each afferent vessel passes to a capsule of Bowman. On reaching the capsule the vessel forms a capillary mass, the **glomerulus**, which is within the invaginated capsule (Figs. 1016, 1017, 1023, and 1026).



Figs. 1024 and 1025.—Lobar circulation. Interlobar circulation. (Poirier and Charpy.)

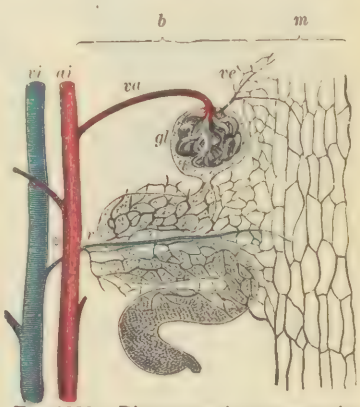


Fig. 1026.—Diagrammatic representation of the blood-vessels in the substance of the cortex of the kidney: *m*, region of the medullary ray; *b*, region of the tortuous portion of the tubules; *ai*, interlobular artery; *vi*, interlobular vein; *va*, vas afferens; *gl*, glomerulus; *ve*, vas efferens; *vz*, venous twig of the interlobularis. (From Ludwig, in Stricker's Handbook.)

[1] Byron Robinson, p. 679.

Emerging from each glomerulus is a small vessel, the **vas efferens** (Figs. 1015, 1016, 1017, 1023, and 1026). This vessel divides into capillaries which are distributed to the tubules of the labyrinth and medullary rays. Blood is gathered from the capillaries about the tubules by veins which correspond to the interlobular arteries and arteriolae recti. These veins form a set of arches across the bases of the pyramids. From the arches veins arise and pass between the pyramids to the sinus of the kidney, where they unite and form branches of the renal vein.

Nerves of the Kidney.—The nerves of the kidney, although small, are about fifteen in number. They have small ganglia developed upon them, and are derived from the **renal plexus**, which is formed by branches from the solar plexus, the lower and outer part of the semilunar ganglion and aortic plexus, and from the lesser and smallest splanchnic nerves. They communicate with the spermatic plexus, a circumstance which may explain the occurrence of pain in the testicle in affections of the kidney. So far as they have been traced, they seem to accompany the renal artery and its branches, but their exact mode of termination is not known.

The Lymphatics.—The lymphatics consist of a **superficial** and **deep set.**

The superficial lymphatics are just beneath the capsule. From them come two sets of collecting trunks (Sappey). One set joins the deep collectors by entering the kidney substance or passing to the hilum. Another set pass into the lymphatics of the fatty capsule.

Fig. 1027.—Fœtal kidney, showing lobes. (Testut.)

The deep collectors emerge from the hilum and lie about the renal artery and vein. From the right kidney some of the trunks pass to the glands about the vena cava and possibly also in the glands in front of the aorta. Others end in the glands back of the vena cava (Stahr).

From the left kidney the trunks pass to the glands which lie along the left side of the abdominal aorta.[1] The lymphatics of the fatty capsule of the kidney pass to the same glands as do the deep collectors of the kidney (Stahr).

Connective Tissue or Intertubular Stroma.—Although the tubules and vessels are closely packed, a certain small amount of connective tissue, continuous with the capsule, binds them firmly together. This tissue was first described by Goodsir, and subsequently by Bowman. Ludwig and Zawarykin have observed distinct fibres passing around the Malpighian bodies, and Henle has seen them between the straight tubes composing the medullary structure.

Variations and Abnormalities.—Congenital absence of the kidney has been observed. Not unusually one kidney is considerably larger than the other; occasionally one is very large and the other is very small, from atrophy, the large organ having become large in response to a functional need, which causes it to compensate for the insufficiency of the small kidney. If a kidney is removed surgically, the other kidney enlarges. As previously stated, the kidneys of the fœtus and of the young child show distinct fissures which makes each organ lobulated (Fig. 1027). The adult kidneys frequently exhibit remains of these fissures. A **horseshoe kidney** is a condition in which the lower poles of the two kidneys are united by kidney structure, the bond of union crossing the middle line. The strip of kidney tissue which effects the junction may be slight in amount,

[1] The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.

considerable, or extensive. Sometimes the two kidneys are completely fused together into one large organ with two ureters.

Surface Form. The kidneys, being situated at the back part of the abdominal cavity and deeply placed, cannot be felt unless enlarged or misplaced. They are situated on the confines of the epigastric and umbilical regions internally, with the hypochondriac and lumbar regions externally. The left is somewhat higher than the right. According to Morris, the position of the kidney may be thus defined: *Anteriorly:* "1. A horizontal line through the umbilicus is below the lower edge of each kidney. 2. A vertical line carried upward to the costal arch from the middle of Poupart's ligament has one-third of the kidney to its outer side and two-thirds to its inner side—*i. e.*, between this line and the median line of the body." In adopting these lines it must be borne in mind that the axes of the kidneys are not vertical, but oblique, and if continued upward would meet about the ninth dorsal vertebra. *Posteriorly:* The upper end of the left kidney would be defined by a line drawn horizontally outward from the spinous process of the eleventh dorsal vertebra, and its lower end by a point two inches above the iliac crest. The right kidney would be half to three-quarters of an inch below. Morris lays down the following rules for indicating the position of the kidney on the posterior surface of the body: "1. A line parallel with, and one inch from, the spine, between the lower edge of the tip of the spinous process of the eleventh dorsal vertebra and the lower edge of the spinous process of the third lumbar vertebra. 2. A line from the top of this first line outward at right angles to it for two and three-quarter inches. 3. A line from the lower end of the first transversely outward for two and three-quarter inches. 4. A line parallel to the first and connecting the outer extremities of the second and third lines just described."

The hilum of the kidney lies about two inches from the middle line of the back, at the level of the spinous process of the first lumbar vertebra.

Surgical Anatomy.—Cases of *congenital absence* of a kidney, of *atrophy* of a kidney, and of *horseshoe kidney* are of great importance, and must be duly taken into account, when nephrectomy is contemplated. A more common malformation is where the two kidneys are *fused together*. They may be only joined together at their lower ends by means of a thick mass of renal tissue, so as to form a horseshoe-shaped body, or they may be completely united, forming a disk-like kidney, from which two ureters descend into the bladder. These fused kidneys are generally situated in the middle line of the abdomen, but may be misplaced as well.

One or both kidneys may be *misplaced* as a congenital condition, and remain fixed in this abnormal position. They are then very often misshapen. They may be situated higher or lower than normal or removed farther from the spine than usual or they may be displaced into the iliac fossa, over the sacro-iliac joint, on to the promontory of the sacrum, or into the pelvis between the rectum and bladder or by the side of the uterus. In these latter cases they may give rise to very serious trouble. The kidney may also be misplaced as a congenital condition, but may not be fixed. It is then known as a *floating kidney*. It is believed to be due to the fact that the kidney is completely enveloped by peritoneum, which then passes backward to the spine as a double layer, forming a *mesonephron*, which permits of movement taking place. The kidney may also be misplaced as an acquired condition; in these cases the kidney is mobile in the tissues by which it is surrounded, either moving in or moving with its fatty capsule. This condition is known as *movable kidney* (*nephroptosis*), and is more common in the female than in the male, and on the right than the left side. If a displaced kidney becomes fixed in an abnormal position, it is said to be *dislocated*. Movable kidney cannot be distinguished from floating kidney until the kidney is exposed by incision. Other malformations are the persistence of the fœtal lobulation; the presence of two pelves or two ureters to the one kidney. In some rare instances a third kidney may be present.

The kidney is embedded in a large quantity of loose fatty tissue, and is but partially covered by peritoneum; hence, *rupture* of this organ is not nearly so serious an accident as rupture of the liver or spleen, since the extravasation of blood and urine which follows is, in the majority of cases, outside the peritoneal cavity. Occasionally the kidney may be *bruised* by blows in the loin or by being compressed between the lower ribs and the ilium when the body is violently bent forward. This is followed by a little transient *hæmaturia*, which, however, speedily passes off. Occasionally, when rupture involves the pelvis of the kidney or the commencement of the ureter, this duct may become blocked, and *hydronephrosis* follows.

The loose cellular tissue around the kidney may be the seat of suppuration, constituting *perinephritic abscess*. This may be due to injury, to disease of the kidney itself, or to extension of inflammation from neighboring parts. The abscess may burst into the pleura, causing empyema; into the colon or bladder; or may point externally in the groin or loin. *Tumors of the kidney*, of which, perhaps, *sarcoma* in children is the most common, may be recognized by their position and fixity; by the resonant colon lying in front of it; by their not moving with respiration; and by their rounded outline, not presenting a notched anterior margin like the spleen, with which they are most likely to be confounded. The *examination of the kidney* should be bimanual; that is to say, one hand should be placed in the flank and firm pressure made forward, while

the other hand is buried in the abdominal wall, over the situation of the organ. Manipulation of the kidney frequently produces a peculiar sickening sensation and some faintness.

The kidney has, of late years, been frequently attacked surgically. It may be exposed and opened for exploration or the evacuation of pus (*nephrotomy*); it may be incised for the removal of stone (*nephro-lithotomy*); it may be sutured when wounded (*nephrorrhaphy*); it may be fixed in place by sutures (*nephropexy*) or gauze pads when movable or floating; or it may be removed (*nephrectomy*).

The kidney may be exposed either by a *lumbar* or *abdominal incision*. The operation is best performed by a lumbar incision, except in a case of very large tumor or of wandering kidney with a loose mesonephron, on account of the advantages which it possesses of not opening the peritoneum and of affording admirable drainage. It may be performed either by an oblique a vertical, or a transverse incision. A common incision for exposing the kidney begins an inch below the twelfth rib at the margin of the Erector spinae muscle and passes obliquely downward and forward, exposing the anterior border of the Latissimus dorsi and the posterior border of the Internal oblique. The surgeon divides the posterior leaflet of the lumbar fascia, draws aside or incises the Quadratus lumborum, and cuts the anterior leaflet of the lumbar fascia and also the transversalis fascia. He opens the fatty capsule down to the kidney and strips it from the true capsule, bringing the kidney outside of the body for inspection. The vertical incision at the edge of the Erector spinae muscle is frequently used. A gridiron or muscle-splitting operation is used by some in order to avoid the division of nerves, vessels, and muscular fibre.

The abdominal operation is best performed by an incision in the linea semilunaris on the side of the kidney to be removed, as recommended by Langenbuch; the kidney is then reached from the outer side of the colon, ascending or descending, as the case may be, and the vessels of the colon are not interfered with. If the incision were made in the linea alba, the kidney would be reached from the inner side of the colon, and the vessels running to supply the colon would necessarily be interfered with. The incision is made of varying length according to the size of the kidney and commences just below the costal arch. The abdominal cavity is opened. The intestines are held aside, and the outer layer of the mesocolon incised, so that the fingers can be introduced behind the peritoneum and the renal vessels are sought for. These vessels are then to be ligatured: if tied separately, care must be taken to ligature the artery first. The kidney must now be enucleated, and the vessels and the ureter divided, and the latter disinfected and tied, and, if it is thought necessary, stitched to the edge of the wound.

THE URETER (Figs. 1004, 1005, 1006, 1011, 1028, 1029).

The ureters are the two tubes which conduct the urine from the kidneys into the bladder. The ureter commences within the sinus of the kidney by a number of short truncated branches, the **calices** or **infundibula**, which unite either directly or indirectly to form a dilated pouch, the **pelvis** (Fig. 1010), from which the ureter, after passing through the hilum of the kidney, descends to the bladder. The **calices** are cup-like tubes encircling the apices of the Malpighian pyramids; but inasmuch as one calyx may include two or even more papillae, their number is generally less than the pyramids themselves. The calices vary in number from eight to eighteen. These calices converge into two or three tubular divisions which by their junction form the **pelvis** or **dilated portion of the ureter**. The portion last mentioned, where the pelvis merges into the ureter proper, is found opposite the spinous process of the first lumbar vertebra, in which situation it is accessible behind the peritoneum (Fig. 1006).

The Ureter Proper.—The ureter proper is a cylindrical membranous tube, about sixteen inches in length and of the diameter of a goosequill, extending from the pelvis of the kidney to the bladder. Its course is obliquely downward and inward through the lumbar region (*pars abdominalis*) (Fig. 1029), into the cavity of the pelvis (*pars pelvina*) (Fig. 1029), where it passes downward, forward, and inward across that cavity to the base of the bladder, into which it then opens by a constricted orifice (*orificium ureteris*) (Fig. 1045), after having passed obliquely for nearly an inch between its muscular and mucous coats (Fig. 1028). The lower part of the abdominal portion of the ureter exhibits a spindle-shaped dilatation.

Relations (Fig. 1029).—In its course it rests upon the Psoas muscle, being covered by the peritoneum, and crossed obliquely, from within outward, by the

spermatic vessels; the right ureter is crossed by the branches of the mesenteric arteries, which are distributed to the ascending colon, and the left ureter by those for the descending colon; the right ureter lying close to the outer side of the inferior vena cava. Opposite the first piece of the sacrum it crosses either the common or external iliac artery and vein, lying behind the ileum on the *right* side and behind the sigmoid flexure of the colon on the *left* side. In the pelvis it enters the posterior false ligament of the bladder, below the obliterated hypogastric artery, the vas deferens in the male passing between it and the bladder. In the female the ureter is to the inner side of the uterine artery at the wall of the pelvis, it passes forward and inward below the posterior layer of the broad ligament running through the parametrium, passing along the side of the neck of the uterus and upper part of the vagina, being in contact with the anterior and lateral vaginal walls and being crossed anteriorly by the uterine artery (Fig. 1099). At the base of the bladder the ureter is situated about two inches from its fellow: lying, in the male, about an inch and a half from the vesical orifice of the urethra, at one of the posterior angles of the trigone (Fig. 1045).

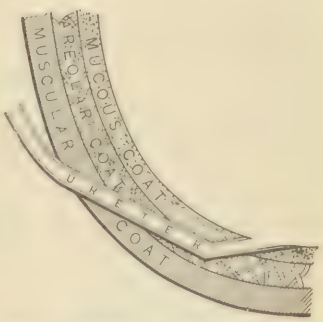

FIG. 1028. Diagram showing method of entrance of the ureter into the bladder. (F. H. Gerrish.)

Structure.—The ureter is composed of three coats—**fibrous**, **muscular**, and **mucous**.

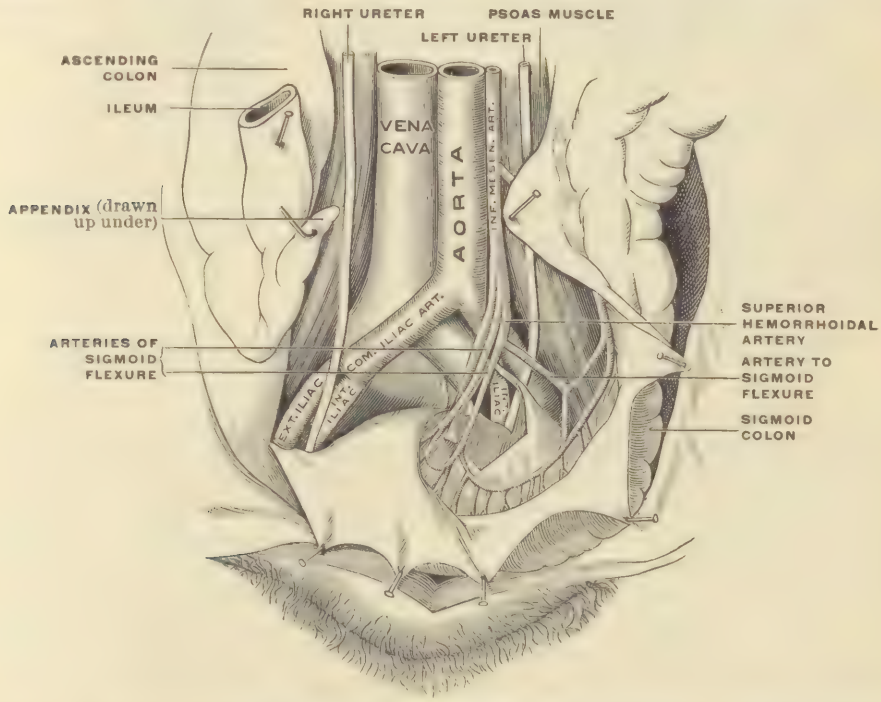

FIG. 1029.—The relations of the pelvic mesocolon with the wall, the iliac sigmoid and superior hemorrhoidal arteries and the ureter. (Poirier and Charpy.)

The Fibrous Coat (*tunica adventitia*).—The fibrous coat is the same throughout the entire length of the duct, being continuous at one end with the fibrous capsule of the kidney at the floor of the sinus, while at the other it is lost in the fibrous structure of the bladder.

The Muscular Coat (*tunica muscularis*).—In the pelvis of the kidney the muscular coat consists of two layers, longitudinal and circular: the **longitudinal** fibres become lost upon the sides of the papillae at the extremities of the calices; the circular fibres may be traced surrounding the medullary structure in the same situation. In the ureter proper the muscular fibres are very distinct, and are arranged in three layers—an **external longitudinal** (*stratum externum*), a **middle circular** (*stratum medium*), and an **internal layer** (*stratum internum*), less distinct than the other two, but having a general longitudinal direction. According to Kölliker, this internal layer is only found in the neighborhood of the bladder.

The Mucous Coat (*tunica mucosa*).—The mucous coat is smooth, and presents a few longitudinal folds which become effaced by distention. It is continuous with the mucous membrane of the bladder below, whilst it is prolonged over the papillae of the kidney above. Its epithelium is of a peculiar character, and resembles that found in the bladder. It is known by the name of **transitional epithelium**. It consists of several layers of cells, of which the innermost—that is to say, the cells in contact with the urine—are quadrilateral in shape, with concave margins on their outer surface, into which fit the rounded ends of the cells of the second layer. These, the intermediate cells, more or less resemble columnar epithelium, and are pear-shaped, with a rounded internal extremity which fits into the concavity of the cells of the first layer, and a narrow external extremity which is wedged in between the cells of the third layer. The external or third layer consists of conical or oval cells varying in number in different parts, and presenting processes which extend down into the basement-membrane.

Vessels and Nerves.—The **arteries** supplying the ureter are branches from the **renal, spermatic, internal iliac,** and **inferior vesical.**

The **nerves** are derived from the **inferior mesenteric, spermatic,** and **pelvic plexuses.**

Surgical Anatomy.—*Subcutaneous rupture* of the ureter is not a common accident, but occasionally occurs from a sharp, direct blow on the abdomen, as from the kick of a horse. The ureter may be either torn completely across, or only partially divided, and, as a rule, the peritoneum escapes injury. If torn completely across the urine collects in the retroperitoneal tissues; if it is not completely divided, the lumen of the tube may become obstructed and hydro-nephrosis or pyo-nephrosis results. The ureter may be accidentally *wounded* in some abdominal operations; if this should happen, the divided ends must be sutured together, or, failing to accomplish this, the upper end must be implanted into the bladder or the intestine.

THE SUPRARENAL CAPSULE OR GLAND (GLANDULA SUPRARENALIS) (Figs. 1010, 1030, 1031).

The suprarenal capsules belong to the class of ductless glands. They are two small flattened bodies, of a yellowish color, situated at the back part of the abdomen, behind the peritoneum, and immediately above and in front of the upper end of each kidney; hence their name. The right one (Fig. 1030) is somewhat triangular in shape, bearing a resemblance to a cocked hat; the left (Fig. 1031) is more semilunar, usually larger and placed at a higher level than the right. They vary in size in different individuals, being sometimes so small as to be scarcely detected; their usual size is from an inch and a quarter to nearly two inches in length, rather less in width, and from two to three lines in thickness. Their average weight is from one to one and a half drachms each.

Relations.—The relations of the suprarenal capsules differ on the two sides of the body.

The Right Suprarenal (Fig. 1030).—The right suprarenal is roughly triangular in shape, its angles pointing upward, downward, and outward. It presents two surfaces for examination, an anterior and a posterior. The **anterior surface** (*facies*

anterior) presents two areas, separated by a furrow, the **hilum** (*hilus glandulae suprarenalis*): one area occupying about one-third of the whole surface, is situated above and internally; it is depressed, uncovered by peritoneum, and is in contact in front with the posterior surface of the right lobe of the liver, and along its inner border with the inferior vena cava; the remaining area is elevated, and is divided into a non-peritoneal portion, in contact with the hepatic flexure of the duodenum, and a portion covered by peritoneum forming the hepato-renal fold. The **posterior surface** (*facies posterior*) is slightly convex, and rests upon the Diaphragm. The **base** (*basis glandulae suprarenalis*) is concave, and is in contact with the upper end and the adjacent part of the anterior surface of the kidney.

The Left Suprarenal (Fig. 1031).—The left suprarenal is crescentic in shape, its concavity being adapted to the upper end of the left kidney. It presents an inner

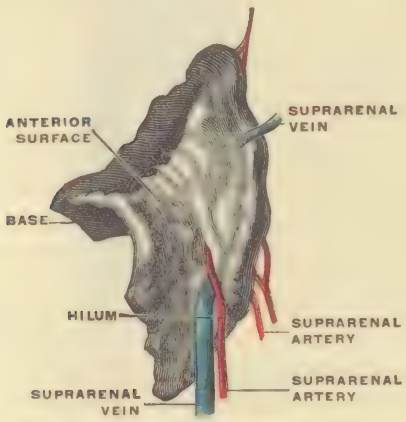

FIG. 1030.—The right suprarenal gland. (Spalteholz.)

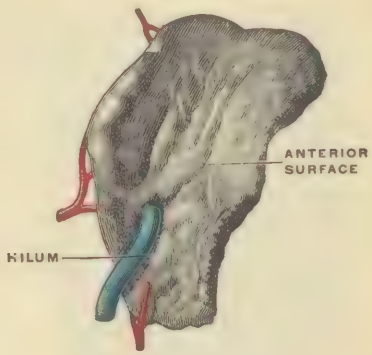

FIG. 1031.—The left suprarenal gland. (Spalteholz.)

border which is convex, and an outer which is concave; its upper border is narrow, and its lower rounded. Its **anterior surface** (*facies anterior*) presents two areas: an upper one, covered by the peritoneum forming the lesser sac, which separates it from the cardiac end of the stomach and to a small extent from the superior extremity of the spleen; and a lower one, which is in contact with the pancreas and splenic artery, and is therefore not covered by the peritoneum. A hilum is present, as in the right suprarenal. Its **posterior surface** (*facies posterior*) presents a vertical ridge, which divides it into two areas. The ridge lies in the sulcus between the kidney and crus of the Diaphragm, while the area on either side of it lies on these parts respectively; the outer area, which is thin, resting on the kidney, and the inner and smaller area resting on the left crus of the Diaphragm. The surface of the suprarenal gland is surrounded by areolar tissue containing much fat, and closely invested by a thin fibrous coat, which is difficult to remove, on account of numerous fibrous processes and vessels which enter the organ through the furrows on its anterior surface and base.

Accessory Suprarenal Glands (*glandulae suprarenales accessoriae*).—Small accessory suprarenals are often to be found in the connective tissue around the suprarenals. The smaller of these, on section, show a uniform surface, but in some of the larger a distinct medulla can be made out.

Structure (Figs. 1032, 1033, and 1034).—On making a perpendicular section (Fig. 1032), the suprarenal gland is seen to consist of two substances—**external** or **cortical** and **internal** or **medullary**. The former, which constitutes the chief part of the organ, is of a deep-yellow color. The medullary substance is soft, pulpy,

and of a dark-brown or black color, whence the name **atrabiliary capsules** formerly given to these organs. In the centre is often seen a space, not natural, but formed by breaking down after death of the medullary substance.

The Cortical Portion (*substantia corticalis*) (Fig. 1032).—The cortical substance consists chiefly of narrow columnar masses placed perpendicularly to the surface. This arrangement is due to the disposition of the capsule, which sends into the interior of the gland processes passing in vertically and communicating with each other by transverse bands so as to form spaces which open into each other. These spaces are of slight depth near the surface of the organ, so that there the section somewhat resembles a net; this is termed the **zona glomerulosa**; but they become much deeper or longer farther in, so as to resemble pipes or tubes placed endwise,

Fig. 1032.—Vertical section of the suprarenal capsule. (From Elberth, in Stricker's Manual.)

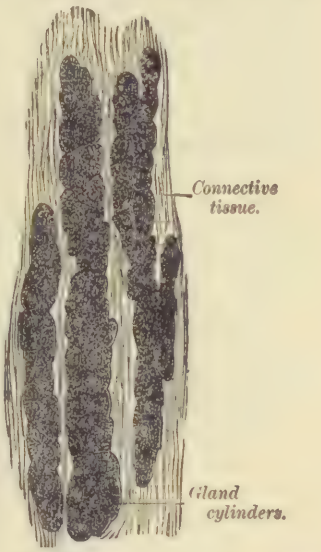

Fig. 1033.—Minute structure of suprarenal capsule.

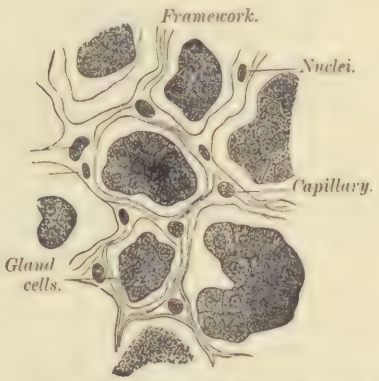

Fig. 1034.—Minute structure of suprarenal capsule.

the **zona fasciculata**. Still deeper down, near the medullary part, the spaces become again of small extent; this is named the **zona reticularis**. These processes or trabeculae, derived from the capsule and forming the framework of the spaces, are composed of fibrous connective tissue with longitudinal bundles of unstriped muscular fibres. Within the interior of the spaces are contained groups of polyhedral cells, which are finely granular in appearance, and contain a spherical nucleus, and not infrequently fat-globules. These groups of cells do not entirely fill the spaces in which they are contained, but between them and the trabeculae of the framework is a channel which is believed to be a lymph-path or sinus, and which communicates with certain passages between the cells composing the

group. The lymph-path is supposed to open into a plexus of efferent lymphatic vessels which are contained in the capsule.

The Medullary Portion (*substantia medullaris*) (Fig. 1032).—In the medullary portion the fibrous stroma seems to be collected together into a much closer arrangement, and forms bundles of connective tissue which are loosely applied to the large plexus of veins of which this part of the organ mainly consists. In the interstices lie a number of cells compared by Frey to those of columnar epithelium. They are coarsely granular, do not contain any fat-molecules, and some of them are branched. Luschka has affirmed that these branches are connected with the nerve-fibres of a very intricate plexus which is found in the medulla; this statement has not been verified by other observers, for the tissue of the medullary substance is less easy to make out than that of the cortical, owing to its rapid decomposition.

Vessels and Nerves.—The numerous arteries which enter the suprarenal bodies from the sources mentioned below penetrate the cortical part of the gland, where they break up into capillaries in the fibrous septa, and these converge to the very numerous veins of the medullary portion, which are collected together into the suprarenal vein, which usually emerge as a single vessel from the centre of the gland.

The **arteries** supplying the suprarenal capsules are three in number and of large size; they are derived from the **aorta,** the **phrenic,** and the **renal**; they subdivide into numerous minute branches previous to entering the substance of the gland.

The **suprarenal vein** returns the blood from the medullary venous plexus, and receives several branches from the cortical substance; it emerges from the hilum and opens on the right side into the inferior vena cava, on the left side into the renal vein.

The **lymphatics** form several collections which are about the beginning of the suprarenal vein. They terminate in the glands to the corresponding side of the aorta.

The **nerves** are exceedingly numerous, and are derived from the **solar** and **renal plexuses,** and, according to Bergmann, from the **phrenic** and **pneumogastric nerves.** They enter the lower and inner part of the capsule, traverse the cortex, and terminate about the cells of the medulla. They have numerous small ganglia developed upon them, from which circumstance the organ has been conjectured to have some function in connection with the sympathetic nervous system.

THE CAVITY OF THE PELVIS.

The cavity of the pelvis is that part of the general abdominal cavity which is below the level of the ilio-pectineal lines and the promontory of the sacrum.

Boundaries.—It is bounded behind by the sacrum, the coccyx, the Pyriformis muscles, and the great sacro-sciatic ligaments; in front and at the sides by the portions of the innominate bones below the ilio-pectineal lines. In front and to the sides the bony sides of the pelvic cavity are partly covered by the internal Obturator muscles, and internal to these muscles by the parietal part of the pelvic fascia. Above, it communicates with the cavity of the abdomen; and below, the outlet is closed by the triangular ligament, the Lævatores ani and Coccygei muscles, and the visceral layer of the pelvic fascia, which is reflected from the wall of the pelvis on to the viscera.

Contents.—The viscera contained in this cavity are—the **urinary bladder,** the **rectum,** and **some of the generative organs** peculiar to each sex, and **some convolutions of the small intestines.** The pelvic viscera are partially covered by the peritoneum, and supplied with blood-vessels, lymphatics, and nerves.

THE URINARY BLADDER (VESICA URINARIA) (Figs. 1037, 1038, 1054, 1055).

The urinary bladder is the reservoir for the urine. It is a musculo-membranous sac situated in the pelvis, behind the pubes, and in front of the rectum in the male, the cervix uteri and vagina intervening between it and that intestine in the female. The shape, position, and relations of the bladder are greatly influenced by age,

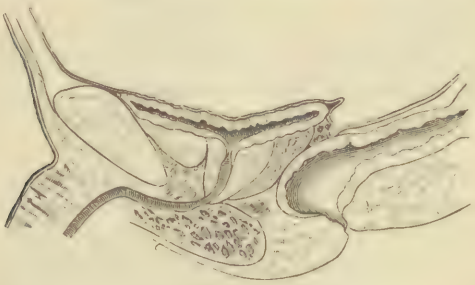

FIG. 1035.—The empty bladder. (Poirier and Charpy.)

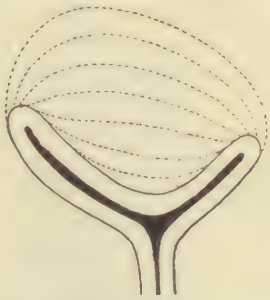

FIG. 1036.—Modifications of form of the bladder during distention (Poirier and Charpy.)

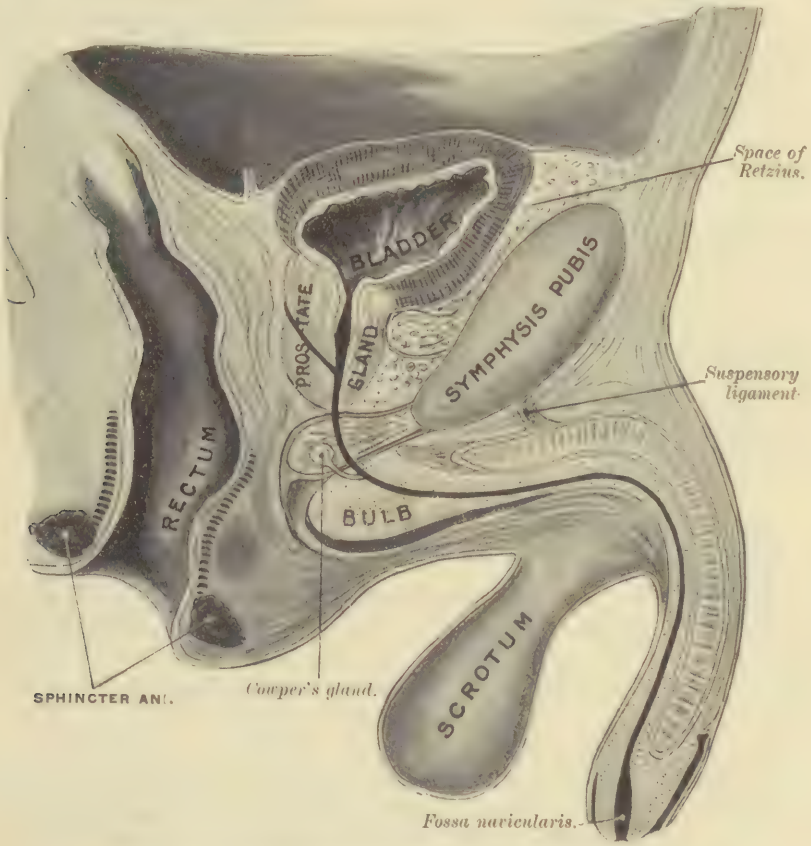

FIG. 1037.—Vertical section of bladder, penis, and urethra.

sex, and the degree of distention of the organ. *During infancy* it is conical in shape, and projects above the symphysis pubis into the hypogastric region. *In the adult*, when quite empty and contracted (Figs. 1035 and 1036), it is cup-shaped, and on vertical median section its cavity, with the adjacent portion of the urethra, presents a Y-shaped cleft, the stem of the Y corresponding to the urethra. It is

placed deeply in the pelvis, flattened from before backward, and reaches as high as the upper border of the symphysis pubis. When slightly distended, it has a rounded form, and is still contained within the pelvic cavity (Fig. 1036), and when greatly distended (Figs. 1036 and 1037), it is ovoid in shape, rising into the abdominal cavity, and often extending nearly as high as the umbilicus. It is larger in its vertical diameter than from side to side, and its long axis is directed from above obliquely downward and backward, in a line directed from some point between the symphysis pubis and umbilicus (according to its distention) to the end of the coccyx. The bladder, when distended, is slightly curved forward toward the

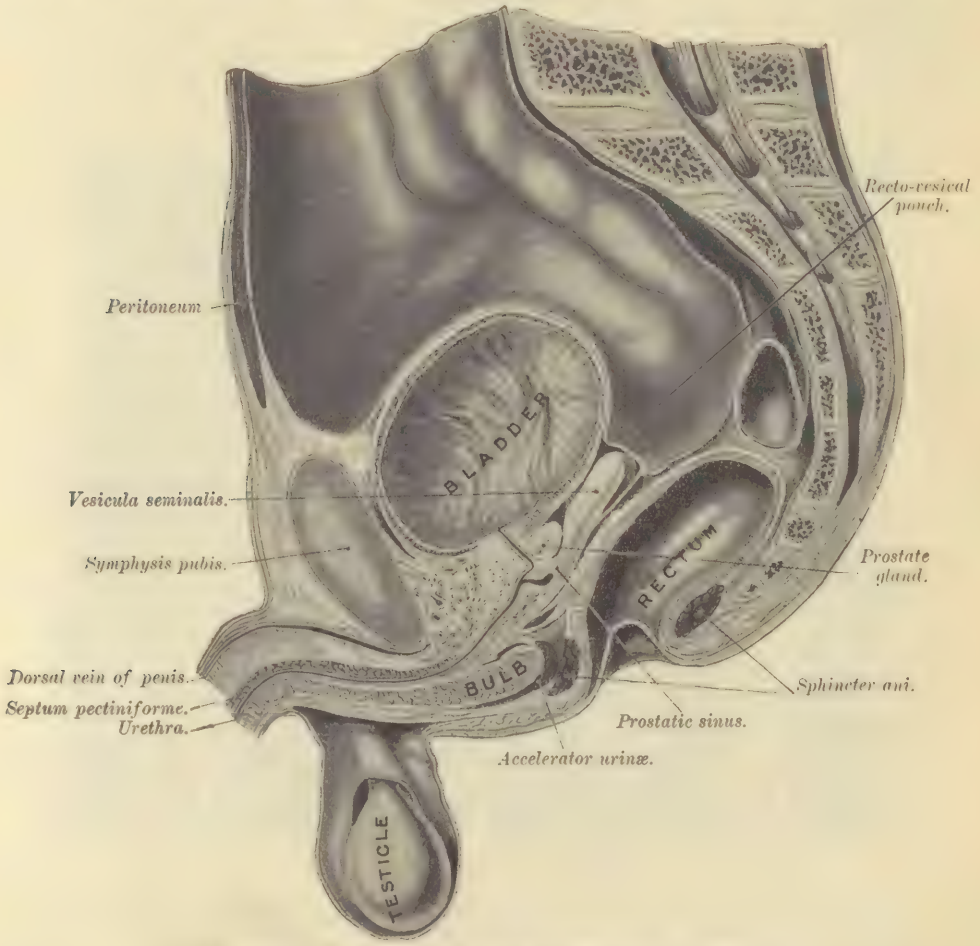

FIG. 1038.—Vertical median section of the male pelvis. (Henle.)

anterior wall of the abdomen, so as to be more convex behind than in front. In the female it is larger in the transverse than in the vertical diameter, and its capacity is said to be greater than in the male.[1] When moderately distended, it measures about five inches in length, and three inches across, and the ordinary amount which it can contain without serious discomfort is about a pint.

The bladder is divided for purposes of description into a **superior**, an **antero-inferior**, and two **lateral surfaces**, a **base** or **fundus**, and a **summit** or **apex**.

Surfaces. The Superior or Abdominal Surface (Figs. 852, 1037, 1038, and 1055). —The superior or abdominal surface is entirely free, and is covered throughout by

[1] According to Henle, the bladder is considerably smaller in the female than in the male.—ED. of 15th English edition.

peritoneum. It looks almost directly upward into the abdominal cavity, and extends in an antero-posterior direction from the apex to the base of the bladder. It is in relation with the small intestine and sometimes with the sigmoid flexure, and, in the female, with the uterus. On each side, in the male, a portion of the vas deferens is in contact with the hinder part of this surface, lying beneath the peritoneum.

The Antero-inferior or Pubic Surface (Figs. 1037, 1038, and 1055).—The antero-inferior or pubic surface looks downward and forward. In the undistended condition it is uncovered by peritoneum, and is in relation with the Obturator internus muscle on each side, with the recto-vesical fascia, and anterior true ligaments of the bladder. It is separated from the body of the pubis by a triangular interval, the **space of Retzius,** occupied by fatty tissue. As the bladder

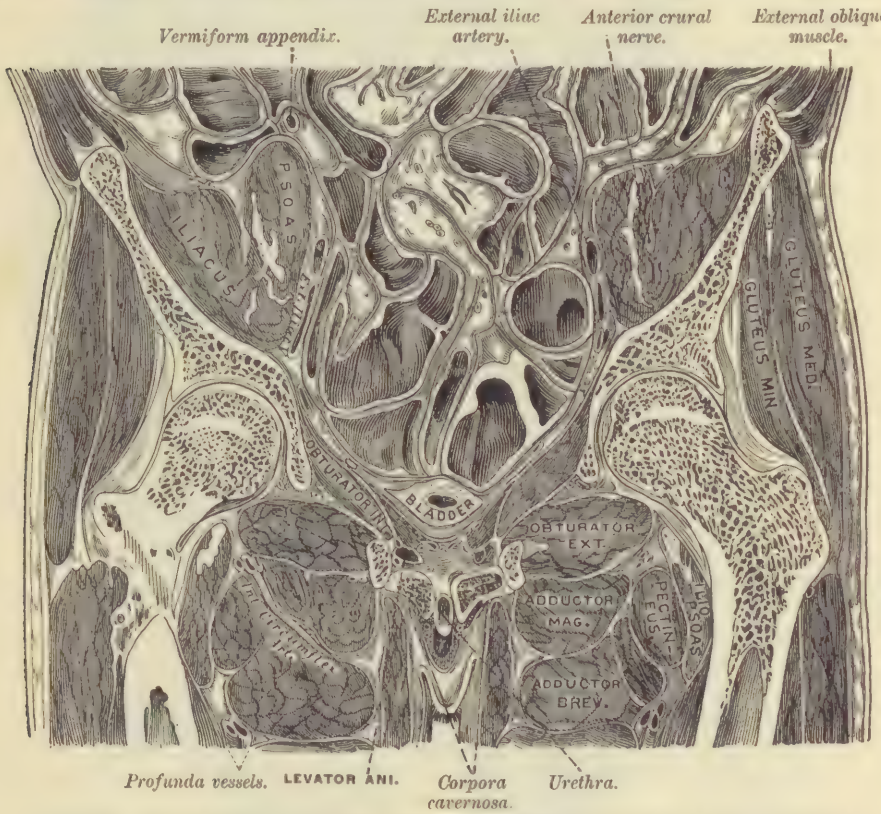

FIG. 1039.—Frontal section of the lower part of the abdomen. Viewed from in front. (Braune.)

ascends into the abdominal cavity during distention the distance between its apex and the umbilicus is necessarily diminished, and the urachus (Fig. 852 and 1055) is thus relaxed; so that, instead of passing directly upward to the umbilicus, it descends first on the upper part of the anterior surface of the bladder, and then, curving upward, ascends on the back of the abdominal wall. The peritoneum, which follows the urachus, thus comes to form a pouch (*plica vesicalis transversa*) of varying depth between the anterior surface of the viscus and the abdominal wall (Fig. 1038). The fold passes to the neighborhood of the internal abdominal rings. Thus, when the bladder is distended, the upper part of its anterior surface is in relation with the urachus and is covered by peritoneum. The lower part of its anterior surface, a distance of about two inches above the symphysis pubis, is devoid of peritoneum, and is in contact with the abdominal wall.

The Lateral Surfaces.—The lateral surfaces are covered behind and above by peritoneum, which extends as low as the level of the obliterated hypogastric artery; below and in front of this, these surfaces are uncovered by peritoneum, and are separated from the Levatores ani muscles and walls of the pelvis by a quantity of loose areolar tissue containing fat. In front this surface is connected to the recto-vesical fascia by a broad expansion on either side, the **lateral true ligaments.** The vas deferens crosses the hinder part of the lateral surface obliquely, and passes between the ureter and the bladder. When the bladder is empty the peritoneum descends on the pelvic wall as low as the lateral border of the bladder and enters a groove known as the **paravesical fossa.** The lateral surfaces, the pubic surface, and the abdominal surface together constitute the **body of the bladder** (*corpus vesicae*).

The Fundus or Base (*fundus vesicae*) (Figs. 1038, 1052, and 1055).—The fundus or base is directed downward and backward, and is partly covered by peritoneum and is in part not covered by it. In the male the upper portion, to within about an inch and a half of the prostate, is covered by the **recto-vesical pouch of peritoneum** (Fig. 855). The lower part is in direct contact with the anterior wall of the second part of the rectum and the vesiculae seminales and vasa deferentia (Figs. 1052 and 1054). The ureters enter the bladder at the upper part of its base, about an inch and a half above the base of the prostate gland (Fig. 1045).

The portion of the bladder in relation with the rectum corresponds to a triangular space, bounded, below, by the prostate gland; above, by the **recto-vesical fold of the peritoneum**; and on each side, by the vesicula seminalis and vas deferens. It is separated from direct contact with the rectum by the **recto-vesical fascia.** When the bladder is very full, the peritoneal fold is raised with it, and the distance between its reflection and the anus is about four inches; but this distance is much diminished when the bladder is empty and contracted. *In the female*, the base of the bladder is connected to the anterior aspect of the cervix uteri by areolar tissue, and is adherent to the anterior wall of the vagina (Fig. 853). Its upper surface is separated from the anterior surface of the body of the uterus by the **utero-vesical pouch of the peritoneum** (Fig. 853).

The so-called **neck** or **cervix of the bladder** (*collum vesicae*) is the point of commencement of the urethra; there is, however, no tapering part, which would constitute a true neck, but the bladder suddenly contracts to the opening of the urethra (Fig. 1038). In the male it is surrounded by the prostate gland and its direction is oblique when the individual is in the erect posture (Figs. 1037 and 1038). In the female its direction is obliquely downward and forward.

The Summit or Apex (*vertex vesicae*).—The summit or apex is the portion of the bladder which when that organ is empty or nearly empty is nearest to the upper border of the symphysis. It is directed upward and forward. In a distended bladder the apex is well above the pubes in the abdominal cavity.

The Urachus or Middle Umbilical Ligament (*ligamentum umbilicale medium*) (Fig. 1055).—The urachus is a connective-tissue cord and is the obliterated remains of the tubular canal of the **allantois,** which existed in the embryo, and a portion of which expanded to form the bladder. It passes upward, from the apex of the bladder, between the transversalis fascia and peritoneum, to the umbilicus, becoming thinner as it ascends. It is composed of fibrous tissue, mixed with plain muscular fibres. The urachus causes the formation of a peritoneal fold, the **plica umbilicalis media** (Fig. 852). On each side of it is placed a fibrous cord, the obliterated portion of the **hypogastric artery,** which, passing upward from the side of the bladder, approaches the urachus above its summit. Over each cord is the fold known as the **plica umbilicalis lateralis** (Fig. 852). In the infant, at birth, the urachus is occasionally found pervious, so that the urine escapes at the umbilicus, and calculi have been found in its canal.

Ligaments.—The bladder is retained in its place by ligaments, which are divided into true and false. The true ligaments are five in number: two anterior, two lateral, and the urachus. The false ligaments, also five in number, are formed by folds of the peritoneum.

The two **anterior true ligaments,** the **pubo-prostatic** or **pubo-vesical ligaments** (*ligamenta puboprostatica*) extend from the back of the ossa pubis, one on each side of the symphysis, to the front of the neck of the bladder, over the anterior surface of the prostate gland. These ligaments are formed by the **recto-vesical fascia,** and contain a few muscular fibres prolonged from the bladder.

The two **lateral true ligaments,** formed by expansions from the fascia lining the lateral wall of the pelvis, are broader and thinner than the preceding. They are attached to the lateral parts of the prostate gland and to the sides of the base of the bladder.

FIG. 1040.—Fibres of the exteral longitudinal layer. (Poirier and Charpy.)

FIG. 1041.—Fibres of the middle or circular layer. (Poirer and Charpy.)

FIG. 1042.—Fibres of the internal longitudinal layer. (Poirier and Charpy.)

The **urachus** or **middle umbilical ligament** is the fibro-muscular cord already mentioned, extending between the summit of the bladder and the umbilicus. It is broad below, at its attachment to the bladder, and becomes narrower as it ascends.

The two **posterior false ligaments** pass forward, in the male, from the sides of the rectum (*plicae rectovesicales*); in the female, from the sides of the uterus (*plicae rectouterinae*), to the posterior and lateral aspect of the bladder; they form in the male the lateral boundaries of the **recto-vesical pouch** (*excavatio rectovesicalis*) (Figs. 926 and 1038); they form in the female the lateral boundaries of the **pouch** or **cul-de-sac of Douglas** (*excavatio rectouterina* [*Douglasi*]) (Figs. 853 and 927). The posterior false ligaments contain the obliterated hypogastric arteries and the ureters, together with vessels and nerves. In the base of each fold is smooth muscle-fibre, the **Recto-vesical muscle** (*m. rectovesicalis*).

The two **lateral false ligaments** are reflections of the peritoneum, from the iliac fossae and lateral walls of the pelvis to the sides of the bladder. Each lateral false ligament (*ligamentum umbilicale laterale*) passes in front into the **plica umbilicalis lateralis** over the corresponding hypogastric artery. The two lateral reflections of peritoneum are continuous in front of the apex vesicae, at which point the peritoneum passes upon the urachus.

The **superior** or **anterior false ligament** or the **suspensory ligament** (*plica umbilicalis media*) is the prominent fold of peritoneum extending from the summit of the bladder to the umbilicus. It is carried off from the bladder by the urachus and the

obliterated hypogastric arteries. The peritoneal fold over each obliterated hypogastric artery is called the **plica umbilicalis lateralis** (Fig. 852), and is the prolongation forward of the ligamentum umbilicale laterale. Besides the true and false ligaments, the bladder receives support from the fibrous tissue and unstriated muscle about the seminal vesicles, and terminations of the ureters and vasa deferentia. In the female the connection with the anterior vaginal wall supports the base of the bladder. In both sexes the most solidly fixed part of the bladder is about the orifice of the urethra.

Structure.—The bladder is composed of four coats—**serous, muscular, submucous,** and **mucous.**

The Serous Coat (*tunica serosa*).—The serous coat is partial, and derived from the peritoneum. It invests the superior surface and the upper part of the lateral surfaces and base, and is reflected from these parts on to the abdominal and pelvic walls.

The Muscular Coat (*tunica muscularis*) (Figs. 1040, 1041, and 1042).—The muscular coat consists of three layers of unstriped muscular fibre: an external layer, composed of fibres having for the most part a longitudinal arrangement; a **middle layer,** in which the fibres are arranged, more or less, in a circular manner; and an **internal layer,** in which the fibres have a general longitudinal arrangement.

The **fibres of the external longitudinal layer** (*stratum externum*) arise from the posterior surface of the body of the os pubis in both sexes (*m. pubovesicalis*), and in the male arise also from the adjacent part of the prostate gland and its capsule. They pass, in a more or less longitudinal manner, up the anterior surface of the bladder, over its apex, and then descend along its posterior surface to its base, where they become attached to the prostate in the male and to the front of the vagina in the female. At the sides of the bladder the fibres are arranged obliquely and intersect one another. The external longitudinal layer has been named the **Detrusor urinae muscle.**

The **middle circular layers** (*stratum medium*) are very thinly and irregularly scattered on the body of the organ, and, though to some extent placed transversely to the long axis of the bladder, are for the most part arranged obliquely. Toward the lower part of the bladder, around the neck and the commencement of the urethra, they are disposed in a thick circular layer, forming the **sphincter vesicae,** which is continuous with the muscular fibres of the prostate gland.

The **internal longitudinal layer** (*stratum internum*) is thin, and its fasciculi have a reticular arrangement, but with a tendency to assume for the most part a longitudinal direction. Two bands of oblique fibres, originating behind the orifices of the ureters, converge to the back part of the prostate gland, and are inserted, by means of a fibrous process, into the middle lobe of that organ. They are the **muscles of the ureters,** described by Sir C. Bell, who supposed that during the contraction of the bladder they served to retain the oblique direction of the ureters, and so prevent the reflux of the urine into them.

The Submucous Coat (*tela submucosa*).—The submucous coat consists of a layer of areolar tissue connecting together the muscular and mucous coats, and intimately united to the latter.

The Mucous Coat (*tunica mucosa*).—The mucous coat is thin, smooth, and of a pale rose color. It is continuous above through the ureters with the lining membrane of the uriniferous tubes, and below with that of the urethra. Except at the trigone, it is connected very loosely to the muscular coat by a layer of areolar tissue, and is therefore thrown into folds or rugae when the bladder is empty (Fig. 1046). The mucous membrane over the trigone never presents rugae. The epithelium covering it is of the transitional variety, consisting of a superficial layer of polyhedral flattened cells, each with one, two, or three nuclei (Fig. 1043); beneath these is a stratum of large club-shaped cells with the narrow extremity of each cell directed downward and wedged in between smaller spindle-shaped cells,

each an oval nucleus (Fig. 1044). There are no true glands in the mucous membrane of the bladder, though certain mucous follicles which exist, especially near the neck of the bladder, have been regarded as such.

Objects Seen on the Inner Surface.—Upon the inner surface of the bladder are seen the **mucous membrane, orifices of the ureters,** the **trigone,** and the **commencement of the urethra.**

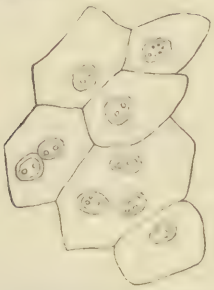

FIG. 1043.—Superficial layer of the epithelium of the bladder. Composed of polyhedral cells of various sizes, each with one, two, or three nuclei. (Klein and Noble Smith.)

FIG. 1044.—Deep layers of epithelium of bladder, showing large club-shaped cells above, and smaller, more spindle-shaped cells below, each with an oval nucleus. (Klein and Noble Smith.)

The Mucous Membrane.—The mucous membrane of the empty bladder is thrown into folds or **rugae,** except over the trigone, where it is firmly adherent to the muscular coat and is smooth (Figs. 1045 and 1046). The folds disappear when the bladder is distended.

The Orifices of the Ureters (Figs. 1045 and 1046).—These are situated at the base of the trigone, being distant from each other about two inches when the bladder is

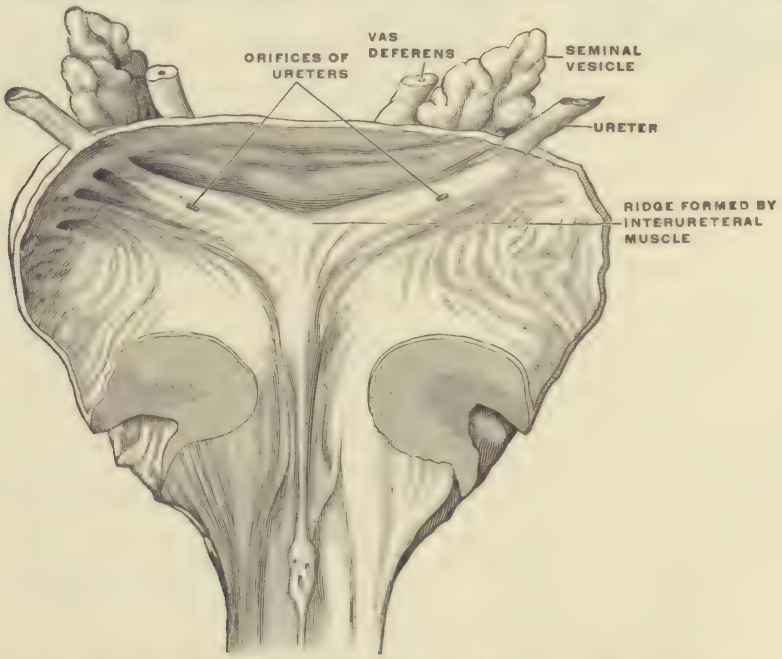

FIG. 1045.—The interior of the bladder, showing the vesical trigone. (Poirier and Charpy.)

moderately distended. Each orifice is about an inch and a half from the base of the prostate and the commencement of the urethra in the moderately distended bladder.

The **Vesical Trigone** or the **Trigonum Vesicae** (Fig. 1045) is a triangular smooth surface, with the apex directed forward, situated at the base of the bladder, immediately behind the urethral orifice. It is paler in color than the rest of the

interior, and never presents any rugae, even in the collapsed condition of the organ, owing to the intimate adhesion of its mucous membrane to the subjacent tissue. It is bounded at each posterior angle by the orifice of a ureter, and in front by the orifice of the urethra. Projecting from the lower and anterior part of the bladder, and reaching to the orifice of the urethra, is a slight elevation of mucous membrane, particularly prominent in old persons, called the **uvula vesicae**. It is formed by a thickening of the submucous tissue.

Stretching from one ureteral opening to the other is a smooth, slightly curved ridge, the convexity of which is toward the urethra. It is produced by transverse muscle-fibres beneath the mucous membrane. The outer prolongations of this ridge beyond the ureteral orifices are called the **ureteral folds** (*plicae ureterícae*). They are created by the ureters as they traverse the bladder wall. About the ureteral orifice are slight radial folds of mucous membrane, which are continuous with the longitudinal folds of the prostatic urethra. "In the empty bladder the ureteral orifice and the openings of the two ureters lie at the angles of an approximately equilateral triangle, whose sides are about one inch in length. When the bladder is distended the distance between the openings may be increased to one and a half inches or more."[1]

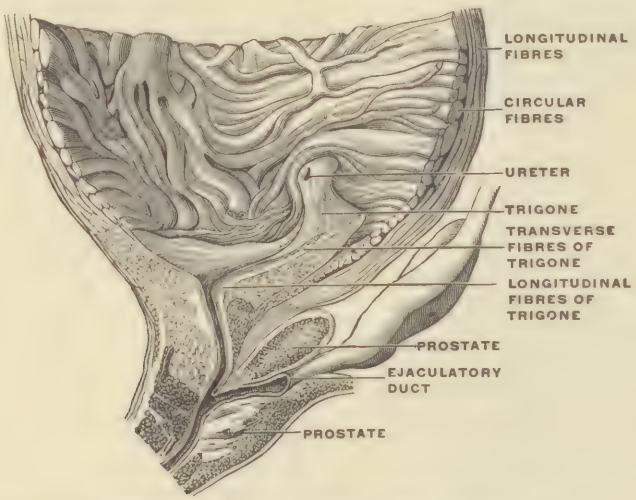

FIG. 1046.—The internal surface of the bladder. (Poirier and Charpy).

The **muscles** of the **ureters** were referred to on p. 1437.

The **internal urethral orifice** (*orificium urethrae internum*) is sickle-shaped and is surrounded by a circular prominence (*annulus urethralis*), which is most distinct in the male.

Vessels and Nerves.—The **arteries** (Fig. 424) supplying the bladder are the **superior, middle,** and **inferior vesical** in the male, with additional branches from the **uterine** and **vaginal** in the female. They are all derived from the **anterior trunk of the internal iliac**. The **obturator** and **sciatic arteries** also supply small visceral branches to the bladder. The **veins** form a complicated plexus around the neck, sides, and base of the bladder (Fig. 474). The veins communicate below with the plexus about the prostate and terminate in the internal iliac vein.

The **lymphatics** form two plexuses, one in the muscular and another in the submucous coat. They accompany the blood-vessels. The mucous membrane of the bladder contains no lymphatics whatever (Sappey). The muscular tissue contains a few lymphatics. The subperitoneal tissues contain the usual number.

[1] Professor A. Francis Dixon, in Prof. D. J. Cunningham's Text-book of Anatomy.

The collecting trunks from the anterior surface terminate in the **external iliac glands**. The trunks from the posterior surface terminate in the **internal iliac glands**, the **hypogastric glands** and the glands in front of the **sacral promontory**.

The **nerves** are derived from the **pelvic plexus of the sympathetic** and from the **third** and **fourth sacral nerves**; the former supplying the upper part of the organ, the latter its base and neck. According to F. Darwin, the sympathetic fibres have ganglia connected with them, which send branches to the vessels and to the muscular coat.

Surface Form.—The surface form of the bladder varies with its degree of distention and under other circumstances. In the young child it is represented by a conical figure, the apex of which, even when the viscus is empty, is situated in the hypogastric region, about an inch above the level of the symphysis pubis. In the adult, when the bladder is empty, its apex does not reach above the level of the upper border of the symphysis pubis, and the whole organ is situated in the pelvis; the neck, in the male, corresponding to a line drawn horizontally backward through the symphysis a little below its middle. As the bladder becomes distended, it gradually rises out of the pelvis into the abdomen, and forms a swelling in the hypogastric region, which is perceptible to the hand as well as to percussion. In extreme distention it reaches into the umbilical region. Under these circumstances the lower part of its anterior surface, for a distance of about two inches above the symphysis pubis, is closely applied to the abdominal wall, without the intervention of peritoneum, so that it can be tapped by an opening in the middle line just above the symphysis pubis, without any fear of wounding the serous membrane. When the rectum is distended, the prostatic portion of the urethra is elongated and the bladder lifted out of the pelvis and the peritoneum pushed upward. Advantage is taken of this by some surgeons in performing the operation of suprapubic cystotomy. The rectum is distended by an India-rubber bag, which is introduced into this cavity empty, and is then filled with ten or twelve ounces of water. If now the bladder is injected with about half a pint of some antiseptic fluid, it will appear above the pubes plainly perceptible to the sight and touch. The peritoneum will be pushed out of the way, and an incision three inches long may be made in the linea alba, from the symphysis pubis upward, without any great risk of wounding the peritoneum. Other surgeons object to the employment of this bag, as its use is not unattended with risk, and because it causes pressure on the prostatic veins and hence produces congestion of the vessels over the bladder and a good deal of venous hemorrhage.

When distended, the bladder can be felt in the male, from the rectum, behind the prostate, and fluctuation can be perceived by a bimanual examination, one finger being introduced into the rectum and the distended bladder being tapped on the front of the abdomen with the finger of the other hand. This portion of the bladder—that is, the portion felt in the rectum by the finger—is uncovered by peritoneum.

Surgical Anatomy. A certain defect of development in which the bladder is implicated is known under the name of *extroversion of the bladder*. In this condition the lower part of the abdominal wall and the anterior wall of the bladder are wanting, so that the posterior surface of the bladder presents on the abdominal surface, and is pushed forward by the pressure of the viscera within the abdomen, forming a red, vascular protrusion, on which the openings of the ureters are visible. The penis, except the glans, is rudimentary and is cleft on its dorsal surface, exposing the floor of the urethra—a condition known as *epispadias*. The pelvic bones are also arrested in development (see page 220).

The bladder may be *ruptured* by violence applied to the abdominal wall when the viscus is distended without any injury to the bony pelvis, or it may be torn in case of fracture of the pelvis. The rupture may be either intraperitoneal or extraperitoneal—that is, may implicate the superior surface of the bladder in the former case, or one of the other surfaces in the latter. Rupture of the antero-inferior surface alone is, however, very rare. Until recently intraperitoneal rupture was uniformly fatal, but now abdominal section and suturing the rent with Lembert sutures often saves the patient. The sutures are inserted only through the peritoneal and muscular coats in such a way as to bring the serous surfaces at the margins of the wound into apposition, and one is also inserted just beyond each end of the wound. The bladder should be tested as to whether it is water-tight before closing the external incision.

The muscular coat of the bladder undergoes *hypertrophy* in cases in which there is any persistent obstruction to the flow of urine. Under these circumstances the bundles of which the muscular coat consists become much increased in size, and, interlacing in all directions, give rise to what is known as the *fasciculated bladder*. Between these bundles of muscular fibres the mucous membrane may bulge out, forming sacculi, constituting the *sacculated bladder*, and in these little pouches phosphatic concretions may collect, forming *encysted calculi*. The mucous membrane is very loose and lax, except over the trigone, to allow of the distention of the viscus.

Various forms of *tumors* have been found springing from the wall of the bladder. The *inno-*

cent tumors are the papilloma and the mucous polypus, arising from the mucous membrane; the fibrous tumor, from the submucous tissue; and the myoma, originating in the muscular tissue; and, very rarely, dermoid tumors, the exact origin of which it is difficult to explain. Of the *malignant tumors*, epitheliomata are the most common, but sarcomata are occasionally found in the bladders of children.

Puncture of the bladder is performed above the pubes without wounding the peritoneum. Puncture by the rectum is not now performed, as a permanent fistula may be left from abscess forming between the rectum and the bladder; or pelvic cellulitis may be set up; moreover, it is exceedingly inconvenient to keep a cannula in the rectum. In some cases in performing this operation the recto-vesical pouch of peritoneum has been wounded, inducing fatal peritonitis. The operation, therefore, has been abandoned. *Suprapubic cystotomy* is considered above under the heading of Surface Form. This operation may be employed to permit of the removal of a calculus and is then called *suprapubic lithotomy*.

THE MALE URETHRA (**URETHRA VIRILIS**) (Figs. 1047, 1048, 1049, 1050, 1054).

The urethra in the male extends from the neck of the bladder at the **internal orifice of the urethra** (*orificium urethrae internum*) to the **meatus urinarius**, the **external orifice of the urethra** (*orificium urethrae externum*), at the end of the penis. The internal orifice has been described (p. 1439). The urethra presents a double curve in the flaccid state of the penis (Fig. 1054), but in the erect state of this organ it forms only a single curve, the concavity of which is directed upward. Its length varies from eight to nine inches; and it is divided into three portions, the **prostatic, membranous**, and **spongy**, the structure and relations of which are essentially different. Except during the passage of the urine or semen, the urethra is a mere cleft or slit, transverse, T-shaped or crescentic (Fig. 1049), with its upper and under surfaces in contact. At the meatus urinarius the slit is vertical, and in the prostatic portion somewhat arched (Fig. 1049).

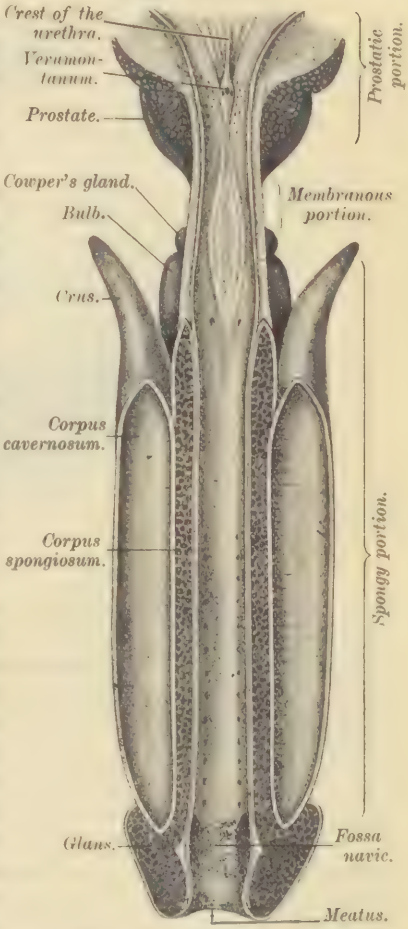

FIG. 1047.—The male urethra, laid open on its anterior (upper) surface. (Testut.)

The First or Prostatic Portion (*pars prostatica*) (Figs. 1037, 1047, 1048, 1055, and 1056).—The first or prostatic portion is the widest and most dilatable part of the canal. It is between the internal orifice of the urethra and the superior layer of the triangular ligament and is within the pelvic cavity. It passes between the two lateral lobes of the prostate gland, from the base to the apex of the gland, lying nearer its anterior than its posterior surface. The gland *seems* to completely surround this portion of the urethra (Fig. 1053), but the glandular matter of the gland does not (Fig. 1051). The gland is like a buckle open in front, and the open part of the buckle is closed by the prostatic muscle. The prostatic urethra is about an inch and a quarter in length; the form of the canal is spindle-shaped, being wider in the middle than at either extremity, and narrowest below, where it joins the membranous portion. Except during the passage of fluid, the canal is in a collapsed state, the anterior wall resting upon the posterior wall (Fig. 1049), and the mucous membrane exhibiting longitu-

dinal folds. When distended, the largest portion of the prostatic urethra has a diameter of about one-third of an inch. A transverse section of the canal as it lies in the prostate is horseshoe-shaped, the convexity being directed forward (Figs. 1049 and 1051). The direction of the canal is nearly vertical, there being a slight curve, which is concave forward (Figs. 1037 and 1038).

Upon the **posterior wall** or **floor** of the canal is a narrow longitudinal ridge, the **crest of the urethra** (*crista urethralis*), formed by an elevation of the mucous membrane and its subjacent tissue (Fig. 1047). This crest begins at the uvula vesicæ, and passes through the prostatic portion and into the membranous portion of the urethra (Fig. 1056), and usually bifurcates at its distal end; it contains, according to Kobelt, muscular and erectile tissues. On this longitudinal ridge is an enlargement, the **verumontanum** or **caput gallinaginis** (*colliculus seminalis*) (Figs. 1047 and 1056). When distended, it may serve to prevent the passage of the semen backward into the bladder. On each side of the verumontanum is a slightly depressed fossa, the floor of which is perforated by numerous apertures, the **orifices of the prostatic ducts** (Figs. 1047 and 1056), from the lateral lobes of the glands; the ducts of the middle

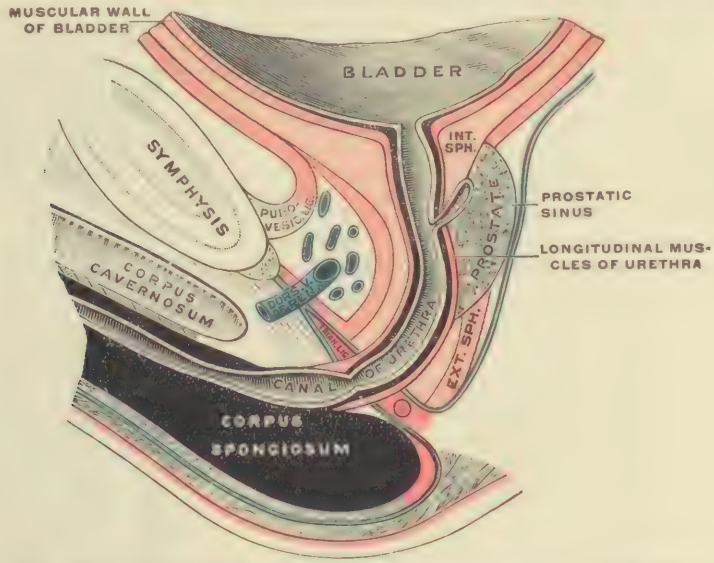

FIG. 1048.—Proximal portions of urethra with surrounding parts. (After Testut.)

lobe open behind the verumontanum. At the forepart of the verumontanum, in the middle line, is a depression, the **prostatic sinus, prostatic utricle, prostatic vesicle, uterus masculinus** or **sinus pocularis** (*utriculus prostaticus*) (Figs. 1038 and 1056); and upon or within its margins are the slit-like openings of the **ejaculatory ducts** (*ductus ejaculatorii*) (Fig. 1056). The sinus pocularis forms a *cul-de-sac* about a quarter of an inch in length, which runs upward and backward in the substance of the prostate behind the transverse band of prostatic tissue which joins the lateral lobes behind the posterior wall of the urethra; its prominent anterior wall partly forms the verumontanum. Its walls are composed of fibrous tissue, muscular fibres, and mucous membrane, and numerous small glands open on its inner surface. It has been called by Weber, who discovered it, the **uterus masculinus**, from its being developed from the united lower ends of the atrophied Müllerian ducts, and therefore being homologous with the uterus and vagina in the female.

The **Second, Muscular** or **Membranous Portion** (*pars membranacea*) (Figs. 1047, 1048, and 1056) extends downward and forward between the apex of the prostate and the bulb of the corpus spongiosum. It is the narrowest part of the canal (excepting the meatus), and measures three-quarters of an inch along its upper, and half an inch along its lower, surface, in consequence of the bulb projecting backward

beneath it. Its anterior concave surface is placed about an inch below and behind the pubic arch, from which it is separated by the dorsal vessels and nerves of the penis, and some muscular fibres. Its posterior convex surface is separated from the rectum by a triangular space, which constitutes the perineum. The membranous portion of the urethra lies chiefly between the inferior and superior layers of the triangular ligament (Fig. 309). The termination of this part of the urethra is overlapped by the **bulb**, and is in front of the triangular ligament (Fig. 309). As it pierces the inferior layer, the fibres around the opening are prolonged over the tube and fix the two structures firmly to each other. The membranous urethra is surrounded by cavernous tissue and by the Compressor urethrae muscle (*m. sphincter urethrae membranaceae*) (Fig. 310). On the floor of the membranous urethra is the anterior extremity of the crista urethralis. Behind this part of the urethra, on each side of the middle line, are **Cowper's glands** (Figs. 308 and 1056). The canal enters the bulb a little in front of the posterior extremity, and the anterior wall or roof of the membranous urethra is a little longer than the posterior wall or floor. The backward projection of the **bulb** hangs over most of the floor of the membranous urethra (Figs. 308, 309, 1047, 1056, and 1058). When the urethra is empty the mucous membrane of the second part is thrown into longitudinal folds, which are obliterated by distention.

The **Third, Penile, Pendulous, Cavernous** or **Spongy Portion** (*pars cavernosa*) (Figs. 1037, 1047, 1048, and 1050) is the longest part of the urethra, and is contained in the corpus

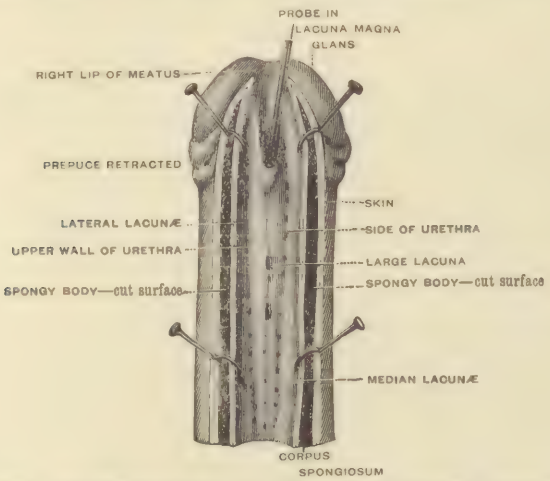

FIG. 1050.—The distal portion of the male urethra, laid open on its posterior (under) surface, showing the lacunae. (Testut.)

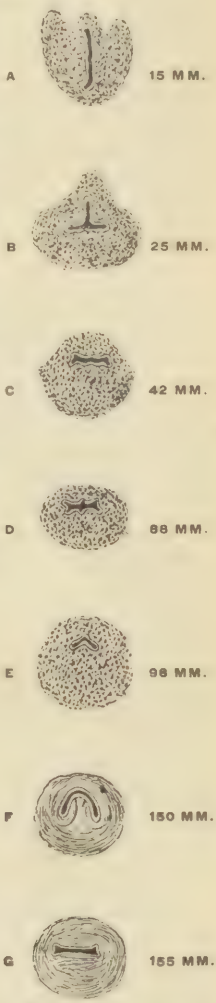

FIG. 1049. — Cross-sections of the male urethra at various distances from its free end, showing marked alterations of form. (Testut.)

spongiosum. It is about six inches in length, and extends from the termination of the membranous portion to the meatus urinarius. It is surrounded throughout its entire course by the erectile tissue of the corpus spongiosum and glans penis. Its proximal end is fixed in position and unchangeable in direction. Its distal end is movable and changeable in direction. Commencing just below the triangular ligament it is first directed forward through the bulb; it then passes downward and forward, the turn beginning at the seat of attachment of the suspensory ligament of the penis (Fig. 1037). The direction of the third portion of the urethra is changed by alterations in the position of the penis. When the canal is closed the anterior and posterior walls are in contact (roof and floor), except in the glans

penis, where the lateral walls come together. "Thus the first part of the canal when empty is represented in cross-section by a transverse slit, and the terminal part by a vertical slit"[1] (Fig. 1049). The calibre of the spongy urethra varies in different portions of the tube. It is of larger diameter in the bulb (bulbous portion of urethra) and in the glans than between these two points. In the body of the penis the canal is of uniform size, and is about one-quarter of an inch in diameter. The **fossa navicularis** (*fossa navicularis urethrae* [*Morgagni*]) is an oblong dilatation of the terminal portion of the penile urethra (Figs. 1037, 1047, and 1060). In the front of the fossa navicularis there is a transverse fold of mucous membrane, the **valve of Guerin** (*valvulae fossae navicularis*). It is part of a distinct depression or pocket. The fossa navicularis opens anteriorly by the **meatus urinarius.**

The **meatus urinarius** or **external orifice of the urethra** (*orificium urethrae externum*) (Figs. 1047 and 1059) is the most contracted part of the urethra; it is a vertical slit (Fig. 1049), about three lines in length, bounded on each side by a small lip or **labium.**

The inner surface of the lining membrane of the urethra, especially on the floor of the spongy portion, presents the orifices of numerous mucous glands (Fig. 1050) situated in the submucous tissue, and named the **glands of Littré** (*glandulae urethrales*). A number of little recesses or follicles, called **lacunae** (*lacunae urethrales*), open into the penile urethra. Some of the glands of Littré open into the lacunae; some do not. They vary in size, and their orifices are directed forward, so that they may easily intercept the point of a catheter in its passage along the canal. One of these lacunae, larger than the rest, is situated in the upper surface of the fossa navicularis, about half an inch from the orifice; it is called the **lacuna magna** (Fig. 1060). Into the bulbous portion are found opening the ducts of Cowper's glands.

Structure.—The urethra is composed of a continuous mucous membrane, supported by a submucous tissue which connects it with the various structures through which it passes.

The Mucous Coat.—The mucous coat forms part of the genito-urinary mucous membrane. It is continuous with the mucous membrane of the bladder, ureters, and kidneys; externally with the integument covering the glans penis; and is prolonged into the ducts of the glands which open into the urethra—viz., Cowper's glands and the prostate gland—into the vasa deferentia and the seminal vesicles through the ejaculatory ducts. The mucous membrane is arranged in longitudinal folds when the tube is empty. Small papillae are found upon it near the orifice, and its epithelial lining is of the columnar variety, excepting near the meatus, where it is squamous.

The Glands and Crypts of the Urethral Mucous Membrane (Fig. 1049).—There is a pocket, the **lacuna magna** (Fig. 1060), opening to the front in the upper wall of the fossa navicularis. The fossa is bounded by the **valve of Guerin** (*valvulae fossa navicularis*). The lacunae of Morgagni are in the spongy urethra back of the valve of Guerin. The lacunae look forward. The largest of them is on the roof of the fossa navicularis, one and one-half inches from the orifice (see above). Some of the lacunae receive the secretion from the glands of Littré; others do not, because some of the glands open on the free surface. The larger lacunae are one-third of an inch deep and are placed in a longitudinal row upon the anterior wall. The smaller lacunae are in longitudinal rows at the sides of the tube. The glands of Morgagni are present throughout the urethra, except in its most anterior part. In the prostatic urethra they are arranged in rows. In the membranous urethra they are scattered irregularly. In the spongy portion they are most numerous on the anterior wall and are more plentiful on the sides than on the floor. Besides the lacunae and racemose glands, there are the opening of the prostatic glands, the ejaculatory ducts, Cowper's glands, and the opening of the sinus pocularis.

[1] Professor A. Francis Dixon, in Professor D. J. Cunningham's Text-book of Anatomy.

The Submucous Tissue.—The submucous tissue consists of a vascular erectile layer. It contains the glands of Littré, especially in the posterior part. These glands are lined with cylindrical epithelium and enter the submucous coat.

The Muscular Layer.—The muscular layer is continuous with the muscle of the prostate and bladder. It is composed of non-striated muscle arranged in an outer layer of **circular fibres** (*stratum circulare*) and an inner layer of **longitudinal fibres** (*stratum longitudinale*). It is placed external to the submucous coat. In the penile urethra there is only a thin layer of longitudinal fibres. In the membranous urethra and the prostatic urethra there are two layers of muscle, an inner thin layer of longitudinal fibres and a thicker layer of circular fibres. The longitudinal fibres, when contracted, shorten the urethra and increase its diameter. The circular fibres are in a state of tonic contraction and close the urethra. In fact, they constitute the real **sphincter** (Zeissl, Zuckerkandl). The so-called sphincter of the urethra, the **Accelerator urinae**, is a voluntary muscle and is not the real sphincter. Outside of the muscular layer of the urethra is the tissue of the corpus spongiosum.

Surgical Anatomy.—The urethra may be *ruptured* by the patient falling astride of any hard substance and striking his perinæum, so that the urethra is crushed against the pubic arch. Bleeding will at once take place from the urethra, and this, together with the bruising in the perinæum and the history of the accident, will at once point to the nature of the injury.

Rupture of the urethra leads to *extravasation of urine*. In rupture back of the superior layer of the triangular ligament the urine usually follows the rectum and reaches the margin of the anus. Rupture between the two layers of the triangular ligament liberates urine between the two layers, where it remains until a path of exit is made by suppuration or the surgeon's knife. In rupture in front of the anterior layer of the ligament the urine passes into the scrotum and may mount up to the abdomen between the symphysis and the pubic spine, between which points the deep layer of the superficial fascia is not attached. It cannot pass to the thigh nor cross the mid-line, because the fascia is attached to the fascia lata and at the mid-line.

The surgical anatomy of the urethra is of considerable importance in connection with the passage of instruments into the bladder. Otis was the first to point out that the urethra is capable of great dilatation, so that, excepting through the external meatus, an instrument corresponding to 18 English gauge (29 French) can usually be passed without damage. The orifice of the urethra is not so dilatable, and therefore may require slitting, although the introduction of the Oberlander dilator, which is expanded after introduction, renders slitting of the meatus seldom necessary in cases of chronic gonorrhœa. A recognition of this dilatability caused Bigelow to very considerably modify the operation of lithotrity and introduce that of litholapaxy. In *passing a fine catheter*, the point of the instrument after it has passed the lacuna magna should be kept as far as possible along the upper wall of the canal, as the point is otherwise very liable to enter one of the lacunæ. *Stricture of the urethra* is a disease of very common occurrence, and is generally situated in the spongy portion of the urethra, most commonly in the bulbous portion, just in front of the membranous urethra, but in a very considerable number of cases in the penile or ante-scrotal part of the canal. Even in a normal urethra, and very markedly in an inflamed urethra, a bougie encounters resistance behind the bulb. This is usually supposed to be due to spasm of the Compressor urethrae muscle.

In *irrigation of the urethra by gravity* fluid tends to block at the same point, especially if it is thrown in suddenly or forcibly. If a reservoir is raised seven and one-half feet from the floor, and if a patient sits on a chair or lies upon a bed, fluid can be readily made to pass by hydraulic pressure from the meatus to the bladder. Spasm may temporarily prevent the inflow, but the weight of the column of fluid soon tires out the muscle and causes it to relax. Relaxation is favored by having the patient take slow, deep breaths and make efforts at urination (Valentine).

Chronic gonorrhœa is frequently kept up by persistent inflammation of the ducts and follicles in the mucous membrane. This condition is known as *chronic glandular urethritis* or *paraurethritis*. In these crypts and glands gonococci may remain when gonorrhœa appears to have passed away, and from time to time reinfection of the urethra may arise from such a source.

Median urethrotomy or *perineal section* is opening of the membranous urethra. Through such an opening the bladder can be drained and explored, and the operation is sometimes called *median cystotomy*.

In *lateral lithotomy* the knife enters the membranous urethra and strikes the groove of the staff. Its edge is then turned toward the left ischial tuberosity and is carried along the groove into the bladder, dividing the membranous urethra, the prostatic urethra, the posterior layer of the triangular ligament, the Compressor urethrae muscle, anterior fibres of the Levator ani muscle and the left lobe of the prostate gland.

THE FEMALE URINARY BLADDER.

The female bladder is situated at the anterior part of the pelvis. It is in relation, *in front*, with the symphysis pubis; *behind*, with the utero-vesical pouch of peritoneum, which separates it from the body of the uterus; its *base* lies in contact with the connective tissue in front of the cervix and upper part of the vagina. *Laterally*, is the recto-vesical fascia. The bladder is said by some anatomists to be larger in the female than in the male. At any rate, it does not rise above the symphysis pubis till more distended than in the male, but this is perhaps owing to the more capacious pelvis rather than to its being of actually larger size. It is described in the section on the Bladder (p. 1431).

THE FEMALE URETHRA (URETHRA MULIEBRIS).

The female urethra is a narrow membranous canal, about an inch and a half in length, extending from the **internal urethral orifice** (*orificium urethrae internum*) at the neck of the bladder to the vestibule of the vagina, where it ends, being called at its termination the **external orifice of the urethra** or the **meatus urinarius** (*orificium urethrae externum*). The meatus is usually a vertical slit. The urethra is placed behind the symphysis pubis, embedded in the anterior wall of the vagina; and its direction is obliquely downward and forward, its course being slightly curved, the concavity directed forward and upward. Its diameter when undilated is about a quarter of an inch. The urethra perforates both layers of the triangular ligament, and its external orifice is situated directly in front of the vaginal opening and about an inch behind the glans clitoridis. Except above, the posterior wall of the urethra is firmly connected to the anterior wall of the vagina.

Structure.—The urethra consists of three coats: **muscular, erectile,** and **mucous.**

The Muscular Coat (*tunica muscularis*).—The muscular coat is continuous with that of the bladder; it extends the whole length of the tube, and consists of an internal layer of **non-striated longitudinal fibres** (*stratum longitudinale*) and an external layer of **non-striated circular fibres** (*stratum circulare*). Superficial to the circular fibres "lies a layer of cross-striped muscle-fibres, which form a closed ring near the bladder only."[1]

The Submucous Coat (*tunica submucosa*).—Internal to the muscular coat is the submucous coat, which contains a venous plexus, networks from which pass between the muscular layers and impart to these layers an erectile or spongy nature (*corpus spongiosum urethrae*). In addition to this, between the two layers of the triangular ligament, the female urethra is surrounded by the Compressor urethrae muscle, as in the male.

The Mucous Coat *tunica mucosa*).—The mucous coat is pale, continuous externally with that of the vulva, and internally with that of the bladder. It is thrown into longitudinal folds, one of which, placed along the floor of the canal, extends from the vesical trigone almost to the external orifice of the urethra. It is called the **crest** (*crista urethralis*). The outline of the urethra is stellate when collapsed, because of the formation of numerous longitudinal folds. It is lined by laminated epithelium, which becomes transitional near the bladder. Many mucous glands open into the urethra, and there are numerous lacunae. External to the external orifice, on each side, a group of mucous glands opens by a common duct, the **ductus para-urethralis.**

The urethra, because it is not surrounded by dense resisting structures, as in the male, admits of great dilatation, which enables the surgeon to remove with considerable facility calculi or other foreign bodies from the cavity of the bladder.

THE MALE ORGANS OF GENERATION.

THE PROSTATE GLAND (PROSTATA) (Figs. 1048, 1051, 1052, 1053, 1054, 1055, 1056, 1057).

THE prostate gland (*προϊστημι, to stand before*) is a structure accessory to the true generative organs and furnishes a viscid, opalescent secretion in which spermatozoids will live (W. G. Richardson). It is a pale, firm, partly glandular and partly muscular body, which is placed immediately below the neck of the bladder and about the commencement of the urethra in the male. The prostate appears to completely surround the first portion of the urethra (Figs. 1053 and 1057), but the glandular matter does not in reality completely surround the tube (Figs. 1051 and 1057). As Spalteholz says, it partly surrounds it as a broad clasp, *open in front*. This opening in the glandular tissue is closed, and a complete ring is established about the urethra by the **prostatic muscle** (*m. prostaticus*) Figs. 1051 and 1057). This muscle below is composed of striated fibres and is continuous with the Compressor urethrae (*m. sphincter urethrae membranacea*);

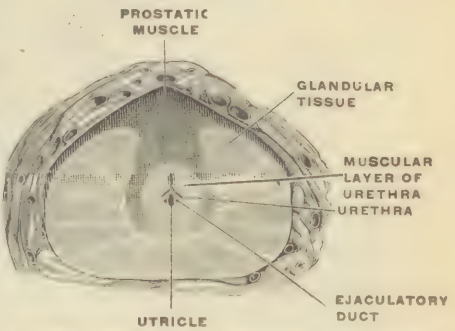

FIG. 1051. Section of the prostate. (Jarjavay.)

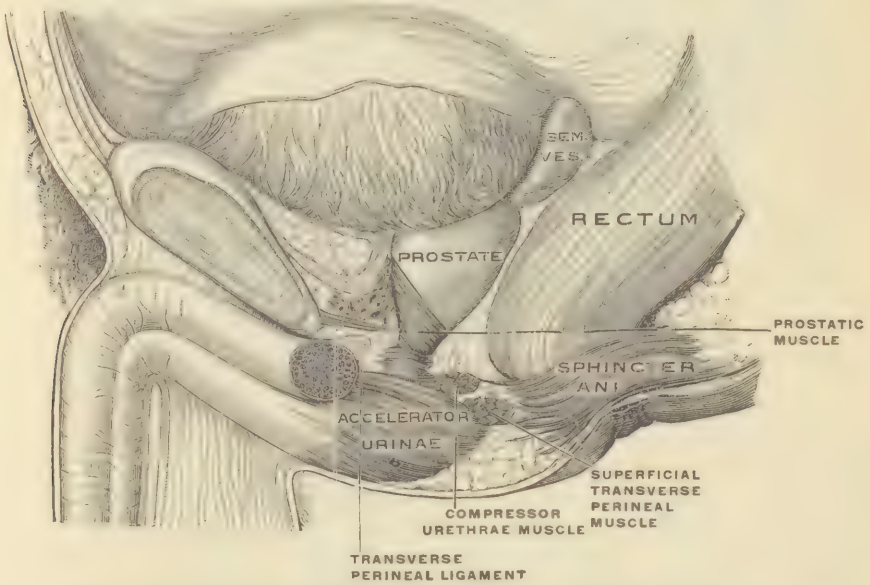

FIG. 1052.—Side view of the position of the prostate. (Poirier and Charpy.)

above it is composed of non-striated muscle, and is continuous with the circular muscular fibres of the bladder which surround the internal urethral orifice and

constitute the Sphincter vesicae (Fig. 1052). The general course of the fibres is transverse, with radiations into the gland substance. The apex of the gland for about one-quarter of an inch is completely surrounded by the muscle (Fig. 1052).

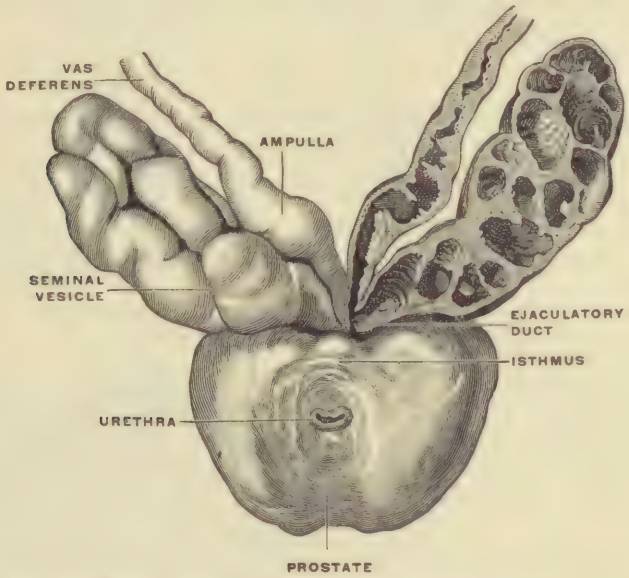

FIG. 1053.—Prostate with seminal vesicles and seminal ducts, viewed from in front and above. (Spalteholz.)

Ascending from the apex the fibres cover for a short distance only the front of the gland and are attached at the sides to the fascia (Fig. 1052). Higher up the muscle

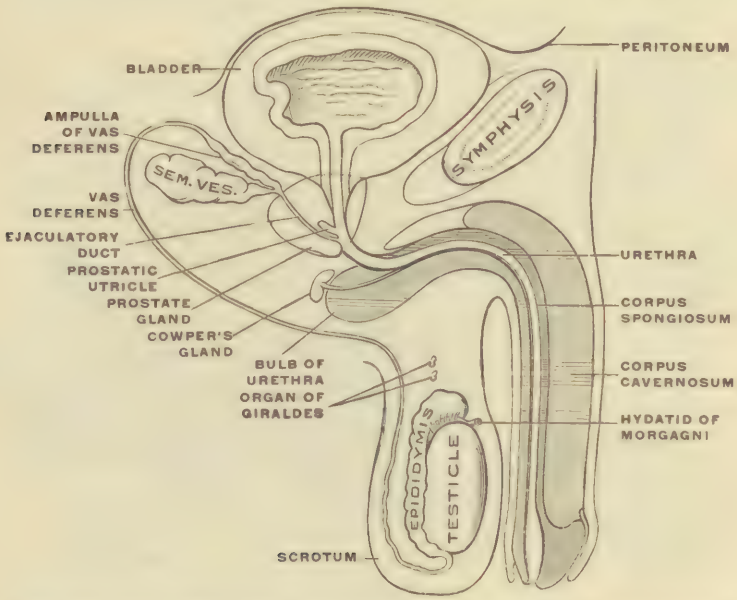

FIG. 1054.—Diagrammatic representation of the male reproduction organs and their relations to the bladder and the urethra. Lateral view. (Toldt.)

passes between the sheath and the capsule and ascends to the base of the prostate, uniting the sheath to the capsule along the mid-line in front. The prostate is placed in the pelvic cavity, behind the lower part of the symphysis pubis, and above the

deep layer of the triangular ligament, and rests upon the rectum, through which it may be distinctly felt, especially when enlarged (Fig. 1055.)

The **ejaculatory ducts** (Figs. 1053, 1054, and 1056) enter the prostate at the margin which separates the base from the posterior surface of the gland; they pass downward, inward, and forward through the prostate, and open into the prostatic urethra. The prostate when surrounded by its sheath resembles a chestnut in shape. When dissected out from its sheath and capsule and from the Prostatic muscle, it resembles an "open clasp" or horseshoe. The **sheath** of the prostate

FIG. 1055.—Sagittal section of the lower part of a male trunk, the right segment. (Testut.)

is derived from the recto-vesical fascia. It is called the **prostatic fascia** (*fascia prostatae*), is distinct and dense, and covers the entire prostate, except at the apex and at the attachment of the base of the prostate to the neck of the bladder. The prostatic fascia is a distinct structure, though it is thin. The veins of the prostatic plexus lie in the layers of the sheath, "and are everywhere separated from the prostatic capsule proper by a layer of this sheath."[1] In an enlarged prostate the sheath is thick and fibrous. It is very difficult to shell out a normal prostate from its sheath, but it is easy to shell out an enlarged prostate. Within the prostatic sheath (which, be it remembered, carries the veins) is the **true** or **proper capsule**

[1] J. W. Thomson Walker, in the British Medical Journal, July 9, 1904.

of the prostate. The true capsule is a continuous investment from the entrance of the urethra above to the triangular ligament below. It is thin, but firm and fibrous. It is not everywhere absolutely distinct from the sheath, but may be fused

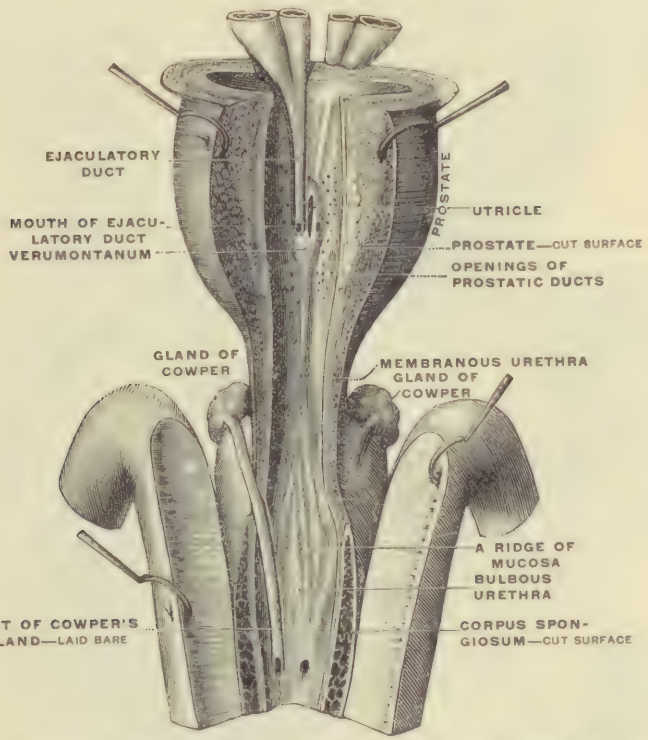

FIG. 1056.—Proximal portion of the urethra, laid open by a median, anterior cut. (Testut.)

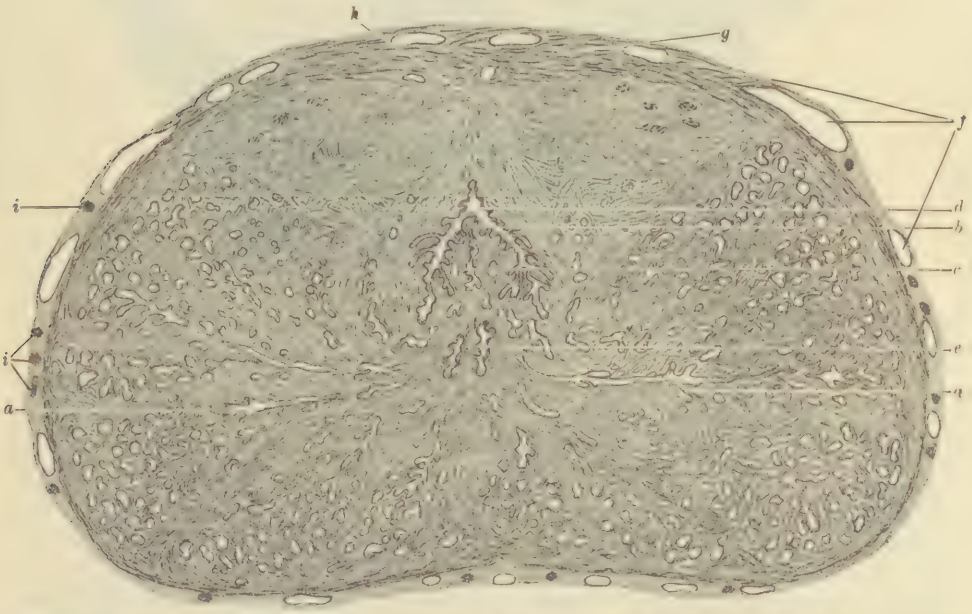

FIG. 1057.—Transverse section of normal prostate through the middle of the verumontanum, from a subject aged nineteen years: *a*, longitudinal section of ducts leading from the lobules of the prostatic glands; *b*, verumontanum; *c*, sinus pocularis; *d*, urethra; *e*, ejaculatory ducts; *f*, arteries, veins, and venous sinuses in sheath of prostate; *g*, nerve trunks in sheath; *h*, point of origin of fibro-muscular bands encircling urethra; *i*, zone of striated voluntary muscle on superior surface. (Drawn from Erdinger projection apparatus.) (Taylor.)

with it here and there, and many bands of fibres run from the sheath to the capsule.[1] The capsule is continuous with the stroma of the gland and cannot be stripped off as can the kidney capsule. Any attempt to strip off the capsule tears away fragments of gland. The capsule is composed of fibrous tissue and unstriated muscle-fibres. From its deep surface the capsule is continuous with the stroma of the prostate (W. G. Richardson). Sir Henry Thompson, half a century ago, pointed out the distinction between true capsule and sheath, and suggested these names. The prostate is divided for study into a **base, apex, posterior surface, anterior surface,** and **lateral surfaces.**

The Base (*basis prostatae*).—The base is directed upward, and is situated immediately below the base of the bladder. It is in contact with and supports the base of the bladder. The external longitudinal muscular layer of the bladder is attached to the posterior portion of the base of the prostate, and some of the fibres reach and adhere to the true capsule. The anterior portion of the base is called the **isthmus** (*isthmus prostatae*) (Fig. 1053).

The Apex (*apex prostatae*).—The apex is directed downward and rests upon the deep layer of the triangular ligament. The apex is fixed, except for the slight mobility of the triangular ligament; the rest of the gland is somewhat movable.

Surfaces.—The Posterior Surface (*facies posterior*).—The posterior surface is flattened, marked by a slight longitudinal furrow, and rests on the second part of the rectum, and is distant about one inch and a half from the anus. At the upper and posterior border of the gland are the seminal vesicles. Their direction is downward and inward; in fact, almost transverse.

The Anterior Surface (*facies anterior*).—The anterior surface is convex, and placed about three-fourths of an inch behind the pubic symphysis, from which it is separated by a plexus of veins and a quantity of loose fat. It is connected to the pubic bone on either side by the **pubo-prostatic ligament.** It is shorter than the posterior surface.

The Lateral Surfaces.—The lateral surfaces are prominent, and are covered by the anterior portions of the **Levatores ani muscles,** which are, however, separated from the gland by a **plexus of veins.**

The prostate measures about an inch and a half transversely at the base, an inch in its antero-posterior diameter, and an inch and a quarter in its vertical diameter. Its weight is about four and a half drachms. It is held in position by the **anterior ligaments of the bladder** (*ligamenta puboprostatica*); by the deep layer of the triangular ligament, which invests the commencement of the membranous portion of the urethra and prostate gland; and by the anterior portions of the Levatores ani muscles, which pass backward from the os pubis and embrace the sides of the prostate. These portions of the Levatores ani, from the support they afford to the prostate, are named the **Levator prostatae.**

The prostate consists of two **lateral lobes** and a **middle lobe.**

The Lateral Lobes (*lobus dexter et sinister*).—The two lateral lobes are of equal size, separated by a deep notch above, and by a furrow upon the anterior and posterior surfaces of the gland, which indicates the bilobed condition of the organ in some animals. At the upper and posterior portion of the prostate the two lobes are united by two bands of gland-tissue. One of these bands is in front of the ejaculatory ducts, the other is below them. "The upper limit of the gland is thus in the form of a horseshoe, open in front."[2] Below the level of the prostatic ducts the prostate and urethra are in relation, but are not closely connected. Above this level the connection is intimate (J. W. Thomson Walker).

The So-called Middle Lobe (*lobus medius*).—The middle lobe is not in reality a lobe, and the name is usually employed to describe an enlargement of the region of the prostate on the posterior portion of the urethra in front of the ejaculatory ducts. The so-called third or middle lobe is an abnormal condition. It is due to enlargement of the transverse band of prostatic tissue which joins the lateral lobes beneath the

[1] W. G. Richardson on the Development and Anatomy of the Prostate Gland.
[2] J. W. Thomson Walker, in the British Medical Journal, July 9, 1904.

base of the bladder, behind the posterior wall of the urethra and in front of the ejaculatory ducts. This mass of tissue is beneath the uvula vesicae. Walker points out that frequently nodules of enlarged prostate protrude into the bladder, being covered only by bladder mucous membrane. This is accomplished by the enlarging prostate forcing its way through the lumen of the vesical sphincter and dilating it, and separating and passing between the strands of the internal longitudinal muscle of the bladder. "The so-called middle lobe is formed by the protrusion of a nodule between the two bands of muscle which pass into the trigone from the ureters, and unite on the posterior wall of the prostatic urethra."[1]

The urethra passes forward between the lateral lobes of the prostate. The prostate is perforated by the ejaculatory ducts. The urethra usually lies on the level of the junction of the anterior and middle thirds of a lateral lobe. The ejaculatory ducts pass obliquely downward and forward through the posterior part of the prostate, and open into the prostatic portion of the urethra.

Structure (Fig. 1057).—As previously stated (p. 1449), the prostate is surrounded by a sheath from the recto-vesical fascia, and possesses also a true capsule.

The glands of the prostate are of the branched tubular variety and number forty or fifty. Many of the ducts join and form from fifteen to twenty-five smaller ducts, which empty into the prostatic urethra, to the sides of the verumontanum (Fig. 1056). The ducts and glands are lined with cubical epithelium. The **prostatic secretion** or **prostatic fluid** (*succus prostaticus*) is a viscid, opalescent, serous secretion, alkaline in reaction, containing a ferment, but no mucus. The substance of the prostate is of a pale, reddish-gray color, of great density and not easily torn. It consists of glandular substance and muscular tissue.

The muscular tissue, according to Kölliker, constitutes the proper stroma of the prostate, the connective tissue being very scanty, and simply forming thin trabeculae between the muscular fibres, in which the vessels and nerves of the gland ramify. The true capsule is continuous with the stroma. The stroma lies between the glandular substance and strands of stroma pass in convergent lines toward the prostatic urethra, especially toward the dorsum of the urethra. These strands or septa divide the prostate into small irregular subdivisions called **lobules.** Next to the urethra, the stroma forms a thick layer. As age advances the interstitial tissue of the prostate increases and the glandular substance shrinks.

Vessels and Nerves.—The **arteries** supplying the prostate are derived from the **internal pudic, inferior vesical,** and **middle haemorrhoidal.** Branches of the vessels enter the gland in the septa between the lobules and send off minute branches to the lobules (Walker). The **veins** form a plexus around the sides and base of the gland between layers of the fascial sheath; they receive in front the **dorsal vein of the penis,** and terminate in the **internal iliac vein.** The **lymphatics** of the prostate begin as networks about the acini of the gland, pass to beneath the capsule, and form another network, and from this peripheral network collecting trunks arise. Several trunks pass from the posterior portion of the gland. One trunk passes to the **external iliac glands,** one to the **internal iliac glands,** and several end in the **lateral sacral glands,** and the **glands of the sacral promontory.** An anterior trunk is joined by lymphatics from the membranous urethra and prostatic urethra and passes to a **gland on the internal pudic artery.**[2] The **nerves** are derived from the **hypogastric plexus.**

Surgical Anatomy.—The *relation of the prostate to the rectum* should be noted: by means of the finger introduced into the gut the surgeon detects enlargement or other disease of the prostate; he can feel the apex of the gland, which is the guide to *Cock's operation* for stricture; he is enabled also by the same means to direct the point of a catheter when its introduction is attended with difficulty either from injury or disease of the membranous or prostatic portions of the urethra. When the finger is introduced into the bowel the surgeon may, in some cases, especially in boys,

[1] J. W. Thomson Walker, in the British Medical Journal, July 9, 1904.
[2] Poirier and Charpy. Human Anatomy.

learn the position, as well as the size and weight, of a calculus in the bladder. In the operation for the removal of a calculus, if, as is not unfrequently the case, the stone should be lodged behind an enlarged prostate, it may be displaced from its position by pressing upward the base of the bladder from the rectum. The prostate gland is occasionally the seat of *suppuration*, either due to injury, gonorrhœa, or tuberculous disease. The gland is enveloped in a dense unyielding capsule, which determines the course of an abscess, and also explains the great pain which is present in acute inflammation. The abscess most frequently bursts into the urethra, the direction in which there is least resistance, but may occasionally burst into the rectum, or more rarely in the perinæum. In advanced life the prostate often becomes considerably *enlarged*, and may project into the bladder so as to impede the passage of the urine. According to Dr. Messer's researches, conducted at Greenwich Hospital, it would seem that such obstruction exists in 20 per cent. of all men over sixty years of age. The prostate may be enlarged by the growth of *innocent tumors*, adenomata, fibromata, myomata, and myofibromata. The entire gland may be *hypertrophied*. A tumor may be encapsulated, but often is surrounded by an area of hyperplasia of prostatic tissues, and usually the area of hyperplasia is much more extensive than the tumor. A tumor may be beneath the mucous membrane, deep in the gland, or beneath the sheath. The growth called the *third lobe* is submucous. In some cases the enlargement affects principally the lateral lobes, which may undergo considerable enlargement without causing much inconvenience. In other cases it would seem that the nodule forms the so-called middle lobe, and even a small enlargement of this character may act injuriously, by forming a sort of valve over the urethral orifice, preventing the passage of the urine, and the more the patient strains, the more completely will it block the opening into the urethra. In consequence of the enlargement of the prostate a *pouch* is formed at the base of the bladder behind the projection, in which urine collects and cannot entirely be expelled. The urine becomes decomposed and ammoniacal, and leads to cystitis. If the prostate enlarges the urethra is lengthened, often dilated, altered in shape, or distorted.

The relation of the enlarged prostate to the neck of the bladder is greatly altered from the relation of the normal prostate. Normally, it is extravesical; when enlarged it may encapsule "the neck of the bladder in a cuff-like manner, extending several inches upward on its wall," and often it protrudes "into the vesical cavity, carrying on its surface the mucosa vesicae."[1] In many cases of prostatic enlargement the gland should be removed (*prostatectomy*). One method is enucleation through a suprapubic incision; another method is enucleation through a perineal incision; another method is carried out by both incisions (the combined method).

The Bottini operation is *prostatotomy*, effected by a special instrument for the purpose of cauterizing the gland and thus causing shrinking.

In elderly individuals the gland tubules may form round, indurated, and sometimes calcified masses, about 1 mm. in diameter, and called *prostatic stones*.

COWPER'S GLANDS (GLANDULAE BULBO-URETHRALES) (Figs. 1056, 1063).

Cowper's glands are two small, rounded, and somewhat lobulated bodies of a yellow color, about the size of peas, placed behind the forepart of the membranous portion of the urethra, between the two layers of the triangular ligament. They lie close above the bulb, and are enclosed by the transverse fibres of the Compressor urethrae muscle. Their existence is said to be constant; they gradually diminish in size as age advances.

Structure.—Each gland consists of several lobules held together by a fibrous investment. Each lobule consists of a number of acini lined by columnar epithelial cells, opening into one duct, which, joining with the ducts of other lobules outside the gland, form a single **excretory duct** (*ductus excretorius*). The excretory duct of each gland, nearly an inch in length, passes obliquely forward beneath the mucous membrane, and opens by a minute orifice on the floor of the bulbous portion of the urethra.

THE PENIS (Figs. 1058, 1059, 1060, 1061, 1062, 1063).

The penis is a long body of prismatic shape placed below and in front of the symphysis pubis. It surrounds the greatest length of the urethra. It consists of a **root**, **body**, and **extremity** or **glans penis**. The root and the posterior portion

[1] John B. Murphy, in the Journal of the American Medical Association, May 28, 1904.

of the body lie beneath the scrotum and the integument of the perinæum (Fig. 1054), and are firmly fixed to the triangular ligament, the pubic bones, and the symphysis; hence this portion of the organ is called the **fixed portion** (*pars fixa*) (Fig. 309). The balance of the organ is free

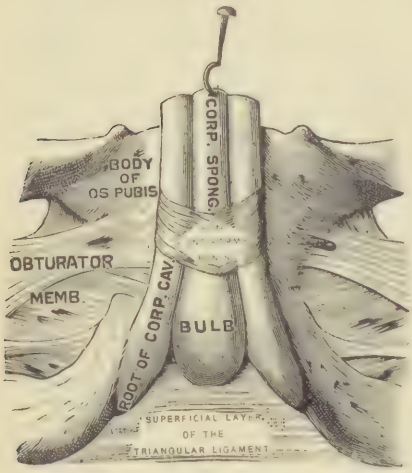

FIG. 1058.—The penis, proximal portion, seen from below. (Testut.)

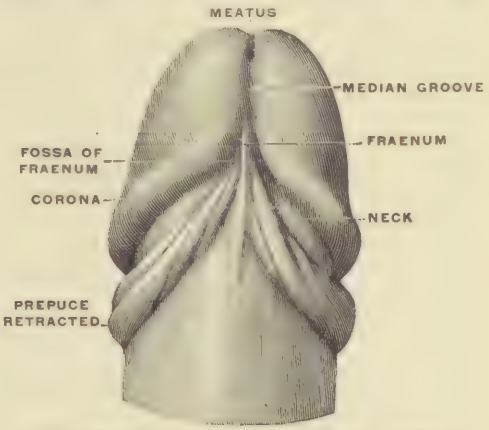

FIG. 1059.—Glans penis, under surface. (Testut.)

and movable (Fig. 1054), and is called the **mobile portion** (*pars mobilis*). When the penis is relaxed there is an angle between the fixed and mobile portions; when the penis is erect, the angle disappears.

The Root (*radix penis*).—The root is firmly connected to the rami of the os pubis and ischium by two strong tapering, fibrous processes, the **crura** (Figs. 1058, 1062, and 1063), and to the front of the symphysis pubis by the **suspensory ligament** (Fig. 1061), a strong band of fibrous tissue which passes downward from the front of the symphysis pubis to the root of the penis.

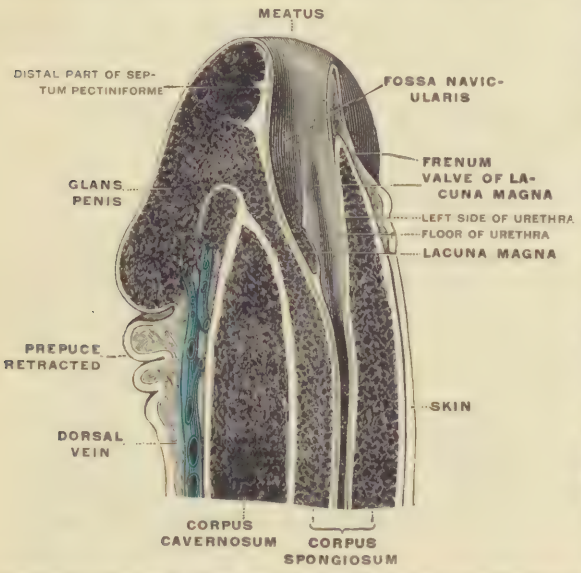

FIG. 1060. The penis, distal end, in sagittal section one-twelfth inch at left of middle line. (Testut.)

The **extremity, acorn** or **glans penis** (Figs. 1059 and 1060) presents the form of an obtuse cone, flattened from above downward. At its summit is a vertical fissure, the **external orifice of the urethra** or the **meatus urinarius** (*orificium urethrae externum*). The base of the glans forms a rounded projecting border, the **corona glandis**, and behind the corona is a deep constriction, the **cervix** or **neck** (*collum glandis*). Upon both the corona and neck numerous small sebaceous glands are found, the **glandulae Tysonii odoriferae.**[1] They secrete a sebaceous matter of very peculiar odor, which probably contains caseine and becomes easily decomposed.

[1] Stieda (Comptes-rendus du XII. Congrès International de Médecine, Moscow, 1897) asserts that Tyson's glands are never found on the corona glandis, and that what have hitherto been mistaken for glands are really large papillae.—ED. of 15th English edition.

The Body of the Penis (*corpus penis*).—The body of the penis is the part between the root and extremity. In the flaccid condition of the organ it is cylindrical, but when erect it has a triangular prismatic form with rounded angles, the broadest side being turned upward, and called the **dorsum penis**. The lower surface of the body of the penis is called the **urethral surface** (*facies urethralis*). The body is covered by integument, and contains in its interior a large portion of the urethra. The integument covering the penis is remarkable for its thinness, its dark color, its looseness of connection with the deeper parts of the organ, and for the absence of adipose tissue. At the root of the penis the integument is continuous with that upon the pubes and scrotum, and at the neck of the glans it leaves the surface and becomes folded upon itself to form the **prepuce** (*præputium*) (Fig. 1059). The internal layer of the prepuce is attached behind to the **cervix** or **neck** (Fig. 1059), and approaches in character to a mucous membrane; from the cervix it is reflected over the glans penis, and at the meatus urinarius is continuous with the mucous lining of the urethra.

The integument covering the glans penis contains no sebaceous glands, but projecting from its free surface are a number of small, highly sensitive papillæ.

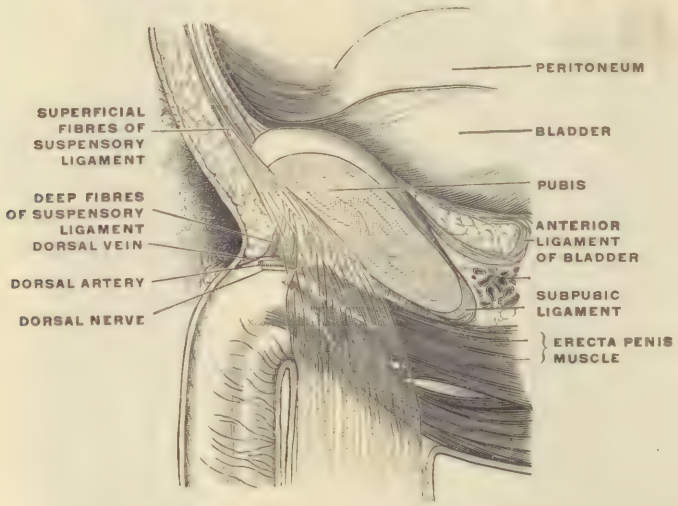

Fig. 1061.—The suspensory ligament. (Poirier and Charpy.)

At the back part of the meatus urinarius a fold of mucous membrane passes backward to the bottom of a depressed raphé, where it is continuous with the prepuce; this fold is termed the **fraenum** (*frenulum præputii*). The skin of the penis covers the mobile parts of the organ. It is thin, extremely elastic, and contains very few hairs. Beneath the skin of the penis is the **dartos layer** (Figs. 1061 and 1068), continuous with the scrotal dartos, containing chiefly non-striated muscular fibres arranged longitudinally. It passes forward to the orifice of the prepuce, and then turns backward, growing thinner and thinner, and finally disappearing at the cervix. Beneath the dartos and extending forward to the orifice of the prepuce is a sheath of **areolar tissue.** It is a lax sheath rich in elastic tissue and containing almost no fat. The superficial vessels and nerves are in the areolar sheath. Beneath the areolar sheath of the penis, from the corona to the root, is the **fascia of the penis** (*fascia penis*) (Fig. 1068). It covers the organ from the root to the corona, and also covers the dorsal artery, veins, and nerves. It is continuous behind with the superficial perineal fascia and suspensory ligament. It is composed chiefly of elastic tissue.

Structure of the Penis.—The penis is composed of a mass of erectile tissue enclosed in three cylindrical fibrous compartments. Of these, two, the **corpora**

cavernosa, are placed side by side along the upper part of the organ; the third, or **corpus spongiosum**, encloses the urethra and is placed below.

The Two Corpora Cavernosa (*corpora cavernosa penis*) (Figs. 1062 and 1063).—The two corpora cavernosa form the chief part of the body of the penis. They consist of two fibrous cylindrical tubes, placed side by side, and intimately connected along the median line for their anterior three-fourths, whilst at their back part they separate from each other to form the **crura penis**, which are two strong tapering fibrous processes or **roots** firmly connected to the rami of the os pubis and ischium (Figs. 1058, 1062, and 1063). Each **crus** commences by a

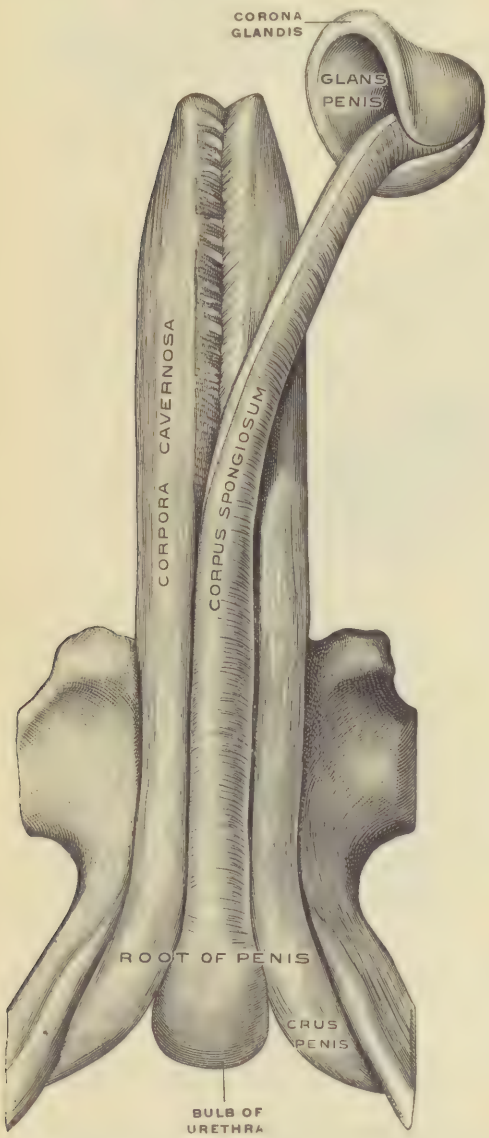

FIG. 1062.—The penis, with the pubic bones, seen from before and below. (Toldt.)

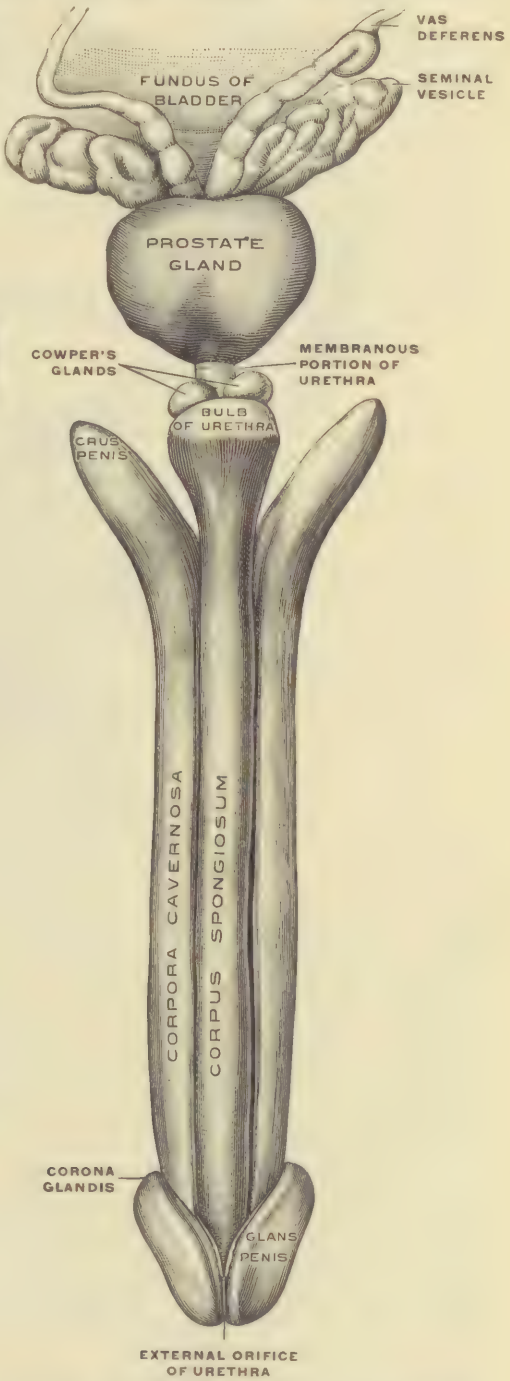

FIG. 1063.—The penis, with the urethra, Cowper's glands, the prostate gland, and the seminal vesicles, seen from below and behind. (Toldt).

blunt-pointed process in front of the tuberosity of the ischium, and before its junction with its fellow to form the body of the penis it presents a slight enlargement, named by Kobelt the **bulb of the corpus cavernosum.** Just beyond this point they become constricted, and retain an equal diameter to their anterior extremity, where they form a single rounded end which is received into a fossa in the base of the glans penis (Figs. 1060 and 1062). A median groove on the upper surface lodges the dorsal arteries, nerves, and veins of the penis (Figs. 1066, 1067, and 1068), and the groove on the under surface receives the corpus spongiosum (Fig. 1062). The root of the penis is connected to the symphysis pubis by the suspensory ligament.

Structure (Fig. 1068).—Each corpus cavernosum is composed of erectile tissue. The erectile tissue is surrounded by a strong fibrous envelope, the **tunica albuginea, corporum cavernosum,** consisting of two sets of fibres—the one, longitudinal in direction, being common to the two corpora cavernosa, and investing them in a common covering; the other, internal, circular in direction, and being proper to each corpus cavernosum. The internal circular fibres of the two corpora cavernosa form, by their junction in the mesial plane, an incomplete partition or septum, the **septum penis,** between the two bodies.

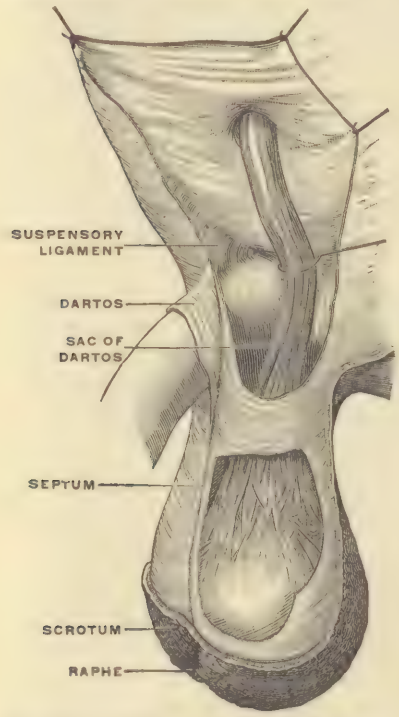

Fig. 1064.—The dartos. (Poirier and Charpy.)

Fig. 1065.—From the peripheral portion of the corpus cavernosum penis under a low magnifying power. 1, *a*, capillary network; *b*, cavernous spaces; 2, connection of the arterial twigs (*a*) with the cavernous spaces. (Copied from Langer.)

The **septum** between the two corpora cavernosa is thick and complete behind, but in front it is incomplete, and consists of a number of vertical bands, which are arranged like the teeth of a comb, whence the name which it has received, **septum pectiniforme.** These bands extend between the dorsal and the urethral surface of the corpora cavernosa. The fibrous investment of the corpora cavernosa is extremely dense, of considerable thickness, and consists of bundles of shining white fibres, with an admixture of well-developed elastic fibres, so that it is possessed of great elasticity.

From the internal surface of the fibrous envelope, as well as from the sides of the septum, are given off a number of bands or cords which cross the interior of each crus in all directions, subdividing it into a number of separate compart-

ments, and giving the entire structure a spongy appearance. These bands and cords are called **trabeculae corporum cavernosum,** and consist of white fibrous tissue, elastic fibres, and plain muscular fibres. In them are continued numerous arteries and nerves.

The component fibres of which the trabeculae are composed are larger and stronger around the circumference than at the centre of the corpora cavernosa; they are also thicker behind than in front. The interspaces, on the contrary, are larger at the centre than at the circumference, their long diameter being directed transversely; they are largest anteriorly. They are called **cavernous spaces** and are occupied by venous blood, and are lined by a layer of flattened cells similar to the endothelial lining of veins (Fig. 1065).

The whole of the structure of the corpora cavernosa contained within the fibrous sheath consists, therefore, of a sponge-like tissue the areolar spaces of which freely communicate with each other and are filled with venous blood. The spaces may therefore be regarded as large cavernous veins.

The arteries bringing the blood to these spaces are the **arteries of the corpora cavernosa** and branches from the **dorsal artery of the penis,** which perforate the fibrous capsule, along the upper surface, especially near the forepart of the organ.

These arteries on entering the cavernous structure divide into branches which are supported and enclosed by the trabeculae. Some of these terminate in a capillary network, the branches of which open directly into the cavernous spaces (Fig. 1065); others assume a tendril-like appearance, and form convoluted and somewhat dilated vessels, which were named by Müller **helicine arteries** (*arteriae helicinae*). They project into the spaces, and from them are given off small capillary branches to supply the trabecular structure. They are bound down in the spaces by fine fibrous processes, and are more abundant in the back part of the corpora cavernosa.

The blood from the cavernous spaces is returned by a series of vessels, some of which emerge in considerable numbers from the base of the glans penis and converge on the dorsum of the organ to form the **deep dorsal vein**; others pass out on the upper surface of the corpora cavernosa and join the dorsal vein; some emerge from the under surface of the corpora cavernosa, and, receiving branches from the corpus spongiosum, wind around the sides of the penis to terminate in the dorsal vein; but the greater number pass out at the root of the penis and join the **prostatic plexus.**

The Corpus Spongiosum (*corpus cavernosum urethrae*) (Figs. 1060, 1062, and 1063).—The corpus spongiosum encloses the urethra, and is situated in the groove on the under surface of the corpora cavernosa penis. It commences posteriorly below the superficial layer of the triangular ligament of the urethra, between the diverging crura of the corpora cavernosa, where it forms a rounded enlargement, the **bulb of the urethra** (*bulbus urethrae*), and terminates anteriorly in another expansion, the **glans penis** (Figs. 1059, 1060, 1062, and 1063), which overlaps the anterior rounded extremity of the corpora cavernosa. The central portion, or body of the corpus spongiosum, is cylindrical, and tapers slightly from behind forward.

The **Bulb of the Urethra** (Figs. 1058, 1062, and 1063) varies in size in different subjects; it receives a fibrous investment from the superficial layer of the triangular ligament, and is surrounded by the Accelerator urinae muscle. The urethra enters the bulb nearer its upper than its lower surface, being surrounded by a layer of erectile tissue, a thin prolongation of which is continued backward around the membranous and prostatic portions of the canal to the neck of the bladder, lying between the two layers of muscular tissue. The portion of the bulb below the urethra presents a partial division into two **lobes** (*hemisphaeria bulbi urethrae*), being marked externally by a linear raphé, whilst internally there projects, for a short distance, a thin **fibrous median septum** (*septum bulbi urethrae*), which is more distinct in early life.

Structure.—The corpus spongiosum consists of a strong fibrous envelope enclosing a trabecular structure, which contains in its meshes erectile tissue. The fibrous envelope is thinner, whiter in color, and more elastic than that of the corpora

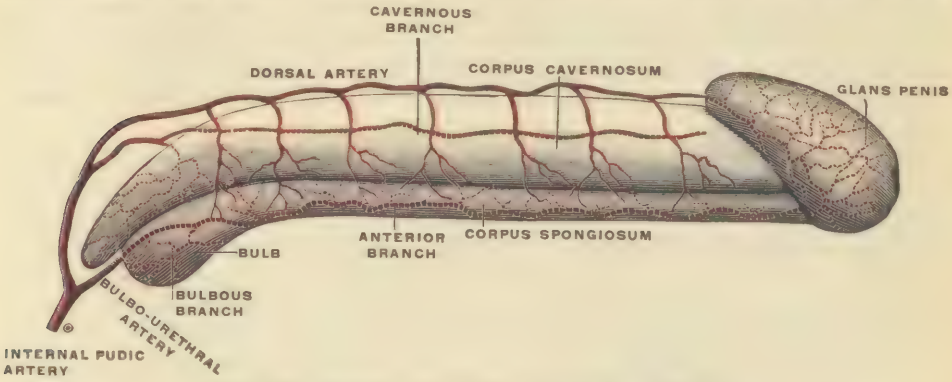

FIG. 1066.—Diagram of the arteries of the penis. (Testut.)

cavernosa of the penis. The trabeculae are more delicate, more nearly uniform in size, and the meshes between them smaller than in the corpora cavernosa, their long diameter, for the most part, corresponding with that of the penis. The external envelope or outer coat of the corpus spongiosum is formed partly of unstriped muscular fibre, and a layer of the same tissue immediately surrounds the canal of the urethra.

Ligaments of the Penis.—The **suspensory ligament** (*ligamentum suspensorium penis*) (Fig. 1061) is firm and fibrous. It passes from the front of the symphysis pubis to the tunica albuginea of the corpora cavernosa. The **ligamentum fundiforme penis** (Fig. 1058), formerly called the suspensory ligament, arises from the linea alba, sheath of the rectus, superficial fascia, and symphysis pubis, and surrounds the penis in a loop, being attached more distalward than is the suspensory ligament, and usually passes into the scrotum. It is composed of elastic tissue.

FIG. 1067.—Veins of the penis. (Testut.)

Vessels and Nerves of the Penis.—The **arteries** (Fig. 1066) of the penis come from branches of the internal pudic artery. The **deep arteries of the penis** give the chief supply to the erectile tissue of the corpora cavernosa, and the dorsal artery also sends branches to it; the **artery of the bulb** (p. 691) supplies the erectile tissue of the corpus spongiosum. The chief blood-supply of the glans is from the **dorsal artery** (p. 692). In the trabeculae the arteries are very small and often twisted. The twisted vessels are called **helicine arteries**. The small arteries open directly into the venous spaces. The veins of the penis empty directly into

the prostatic plexus or into the deep dorsal vein, which empties into the prostatic plexus. On each side of the deep dorsal vein is a dorsal artery and external to each dorsal artery is a dorsal nerve (Fig. 1068). The **superficial dorsal vein** (Figs. 1067 and 1068), receiving small veins from the prepuce, passes back beneath the skin, reaches the symphysis and divides into two branches, each of which passes to the corresponding superficial external pudic vein.

The **lymphatics** of this region have been studied carefully by Poirier, Cunéo, and Delamare,[1] which book I have freely used.

The *lymphatics* of the skin of the penis and prepuce are continuous (Fig. 501). Those on the internal surface of the prepuce are continuous with those of the glans. The trunks of the cutaneous lymphatics anastomose with each other, ascend by the dorsal vein, and terminate in the inguinal glands. The trunks from the glans converge toward the frænum ; they then ascend to the median part of the corona, and the vessels of the two sides unite. Several collectors ascend on the dorsum to the inguinal and femoral glands.

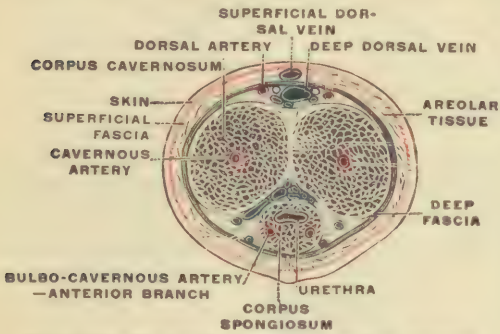

Fig. 1068. The penis in transverse section, showing the blood-vessels. (Testut.)

The superior wall of the anterior portion of the urethra is drained by the lymphatic trunks from the glans. From the rest of the penile urethra the lymphatics unite with the trunks from the penis, and most of them terminate in the same way, although one of them passes between the Recti muscles and terminates in the deeper external iliac glands or in the "internal retro-crural gland."[2]

The trunks from the bulb and membranous urethra terminate in the external iliac glands, the "internal retro-crural gland," and the glands along the internal pudic artery (Poirier, Cunéo, and Delamare). The trunks from the prostatic urethra join the trunks from the prostate gland.

The **nerves** are derived from the internal pudic nerve and the pelvic plexus. On the glans and bulb some filaments of the cutaneous nerves have Pacinian bodies connected with them, and, according to Krause, many of them terminate in a peculiar form of end-bulb.

Surgical Anatomy.—It is occasionally necessary to *remove* a penis for malignant disease. Usually, removal of the ante-scrotal portion is all that is necessary, but sometimes it is requisite to remove the whole organ from its attachment to the rami of the ossa pubis and ischia. The former operation is performed either by cutting off the whole of the anterior part of the penis with one sweep of the knife, or, what is better, cutting through the corpora cavernosa from the dorsum, and then separating the corpus spongiosum from them, dividing it at a level nearer the glans penis. The mucous membrane of the urethra is then slit up, and the edges of the flap attached to the external skin, in order to prevent contraction of the orifice, which would otherwise take place. The vessels which require ligature are the two dorsal arteries of the penis, the arteries of the corpora cavernosa, and the artery of the septum. When the entire organ requires removal the patient is placed in the lithotomy position, and an incision is made through the skin and subcutaneous tissue around the root of the penis, and carried down the median line of the scrotum as far as the perinæum. The two halves of the scrotum are then separated from each other, and a catheter having been introduced into the bladder as a guide, the spongy portion of the urethra below the triangular ligament is separated from the corpora cavernosa and divided, the catheter having been withdrawn just behind the bulb. The suspensory ligament is now severed, and the crura separated from the bone with a periosteum scraper, and the whole penis removed. The membranous portion of the urethra, which has not been removed, is now to be attached to the skin at the posterior extremity of the incision in the perinæum. The remainder of the wound is to be brought together, free drainage being provided for.

THE TESTICLES (TESTES) AND THEIR COVERINGS (Figs. 1071, 1072).

The testicles are two glandular organs, which secrete the semen; they are situated in the scrotum, being suspended by the spermatic cords. At an early period of fœtal life the testes are contained in the abdominal cavity, behind the peritoneum, but they subsequently descend into the scrotum.

DESCENT OF THE TESTIS (DESCENDUS TESTIS).

Each testis at an early period of fœtal life is placed at the back part of the abdominal cavity, behind the peritoneum, in front and a little below the kidney. The anterior surface and sides are invested by peritoneum. At about the third month of intra-uterine life a peculiar structure, the **gubernaculum testis**, makes its appearance. This structure is at first a slender band which extends from the situation of the internal ring to the epididymis and body of the testicle, and is then continued upward in front of the kidney toward the Diaphragm. As development advances the peritoneum covering the testicle encloses it and forms a mesentery, the **mesorchium**, which also encloses the gubernaculum and forms two folds—one above the testicle, and the other below it. The one above the testicle is

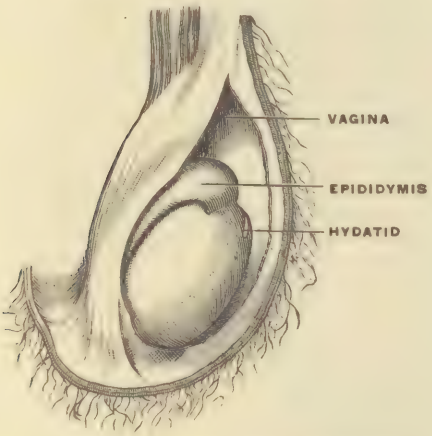

Fig. 1069.—Vaginal tunics of the testicle. (Poirier and Charpy.)

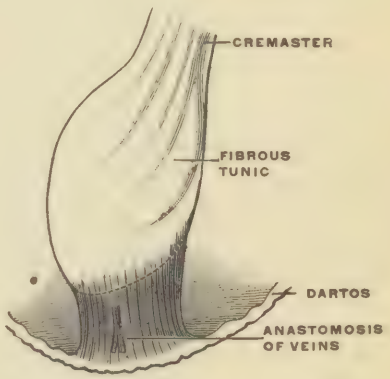

Fig. 1070.—Ligament of the scrotum. (Poirier and Charpy.)

the **plica vascularis**, and contains ultimately the spermatic vessels; the one below, the **plica gubernatrix**, contains the lower part of the gubernaculum, which has now grown into a thick cord; it terminates below at the internal ring in a tube of peritoneum, the **processus vaginalis**, which now lies in the inguinal canal. The lower part of the gubernaculum by the fifth month has become a thick cord, whilst the upper part has disappeared. The lower part can now be seen to consist of a central core of unstriped muscle-fibre, and outside this of a firm layer of striped elements, connected, behind the peritoneum, with the abdominal wall. Later on, about the sixth month, the lower end of the gubernaculum can be traced into the inguinal canal, extending to the pubes, and, at a later period, to the bottom of the scrotum. The fold of peritoneum constituting the processus vaginalis projects itself downward into the inguinal canal, forming a gradually elongating depression or *cul-de-sac*, which eventually reaches the bottom of the scrotum. This *cul-de-sac* is now invaginated by the testicle, as the body of the fœtus *grows*, for the gubernaculum does not grow commensurately with the growth of other parts, and therefore the testicle, being attached by the gubernaculum to the bottom of the

scrotum, is prevented from rising as the body grows, and is drawn first into the inguinal canal, and eventually into the scrotum. By the eighth month the testicle has reached the scrotum, preceded by the lengthened pouch of peritoneum, the processus vaginalis, which communicates by its upper extremity with the peritoneal cavity. Just before birth the upper part of the pouch usually becomes closed, and this obliteration extends gradually downward to within a short distance of the testis. The process of peritoneum surrounding the testis, which is now entirely cut off from the general peritoneal cavity, constitutes the **tunica vaginalis.**[1]

Mr. Jacobson[2] says that the attachments of the gubernaculum above are to the vas, the epididymis, and afterward to the testicle. The lower attachments of the gubernaculum, some of which are temporary, are the abdominal wall, pubes and root of the scrotum, Scarpa's triangle, perinæum and scrotum. The remains of the scrotal fibres constitute a so-called ligament of the scrotum or the **mesorchium,** which causes adhesion between the testicle and skin (Fig. 1070).

In the female, a small cord, corresponding to the gubernaculum in the male, descends to the inguinal region and ultimately forms the round ligament of the uterus. A pouch of peritoneum accompanies it along the inguinal canal, analogous to the processus vaginalis in the male; it is called the **canal of Nuck.**

Surgical Anatomy.—Abnormalities in the formation and in the descent of the testicle may occur. The testicle may fail to be developed, or it may be fully developed and the vas deferens may be undeveloped in whole or in part; or, again, both testicle and vas deferens may be fully developed, but the duct may not become connected to the gland. The testicle may fail in its descent (*cryptorchismus*) or it may descend into some abnormal position (*ectopia testis*). Thus it may be retained in the position where it was primarily developed, below the kidney; or it may descend to the internal abdominal ring, but fail to pass through this opening; it may be retained in the inguinal canal, which is perhaps the most common position; or it may pass through the external abdominal ring and remain just outside it, failing to pass to the bottom of the scrotum. On the other hand, it may get into some abnormal position; it may pass the scrotum and reach the perinæum, or it may fail to enter the inguinal canal, and may find its way through the femoral ring into the crural canal, and present itself on the thigh at the saphenous opening. Ectopia testis is due to the absence, overdevelopment or malposition of some portion of the gubernaculum. There is still a third class of cases of abnormality in the position of the testicle, where the organ has descended in due course into the scrotum, but is malplaced. The most common form of this is where the testicle is *inverted;* that is to say, the organ is rotated, so that the epididymis is connected to the front of the scrotum, and the body, surrounded by the tunica vaginalis, is directed backward. In these cases the vas deferens is to be felt in the front of the cord. The condition is of importance in connection with hydrocele and hæmatocele, and the position of the testicle should always be carefully ascertained before performing any operation for these affections. Again, more rarely, the testicle may be *reversed.* This is a condition in which the top of the testicle, indicated by the globus major of the epididymis, is at the bottom of the scrotum, and the vas deferens comes off from the summit of the organ.

THE COVERINGS OF THE TESTICLE (Fig. 1073).

The coverings of the testicle are the following:

Skin, Dartos } Scrotum.
Intercolumnar or External spermatic fascia.
Cremasteric fascia.
Infundibuliform or Fascia propria (Internal spermatic fascia).
Tunica vaginalis.

The Testicular Bag or Scrotum (Figs. 1071 and 1072).—The testicular bag or scrotum is a cutaneous pouch which contains the testes and part of the spermatic cords. It is divided on its surface into two lateral portions by a median line or

[1] The obliteration of the process of peritoneum which accompanies the cord, and is hence called the *funicular process*, is often incomplete. See section on Inguinal Hernia.
[2] Diseases of the Male Organs of Generation.

raphé (*raphe scroti*), which is continued forward to the under surface of the penis and backward along the middle line of the perinæum to the anus. Of these two lateral portions, the left is usually longer than the right, and corresponds with the usual greater length of the spermatic cord on the left side. Its external aspect varies under different circumstances: thus under the influence of warmth and in old and debilitated persons it becomes elongated and flaccid, but under the influence of cold and in the young and robust it is short, corrugated, and closely applied to the testes. The wrinkles in the scrotum are called **rugae**.

The scrotum consists of two layers, the **integument** and the **dartos**.

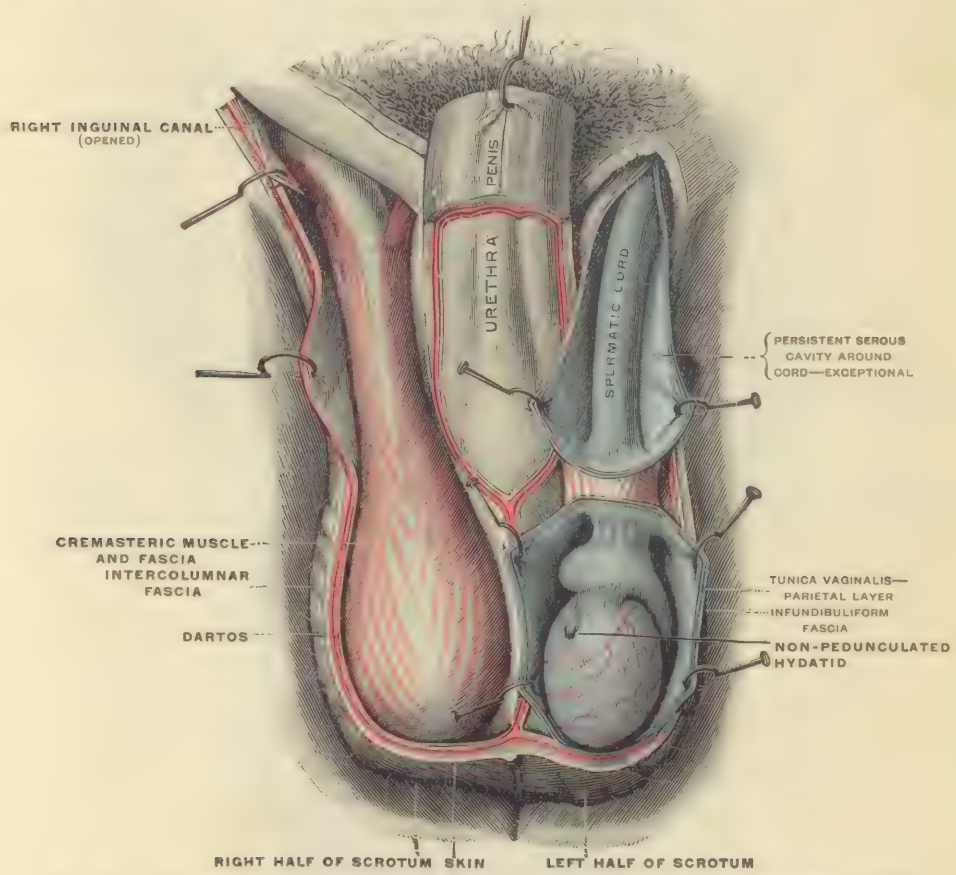

FIG. 1071.—The scrotum. On the left side the cavity of the tunica vaginalis has been opened; on the right side only the layers superficial to the cremaster have been removed. (Testut.)

The Integument.—The integument is very thin, of a brownish color, and generally thrown into folds or rugae. It is provided with sebaceous follicles, the secretion of which has a peculiar odor, and is beset with thinly-scattered, crisp hairs, the roots of which are seen through the skin.

The Dartos (*tunica dartos*) (Figs. 1064 and 1071).—The dartos is a thin layer of loose tissue, endowed with contractility; it forms the proper tunic of the scrotum, is continuous around the base of the scrotum, with the two layers of the superficial fascia of the groin and perinæum, and sends inward a distinct septum, the **septum of the scrotum** (*septum scroti*) (Fig. 1071), which divides it into two cavities for the two testes, the septum extending between the raphé and the under surface of the penis as far as its root.

The dartos is closely united to the skin externally, but connected with the

subjacent parts by delicate areolar tissue, upon which it glides with the greatest facility. The dartos is very vascular, and consists of a loose areolar tissue containing unstriped muscular fibre, but no fat. Its contractibility is slow, and excited by cold and mechanical stimuli, but not by electricity.

The Intercolumnar or Spermatic Fascia (Fig. 1071).—The intercolumnar fascia is a thin membrane derived from the margin of the pillars of the external abdominal ring, during the descent of the testis in the fœtus, which is prolonged downward around the surface of the cord and testis. It is separated from the

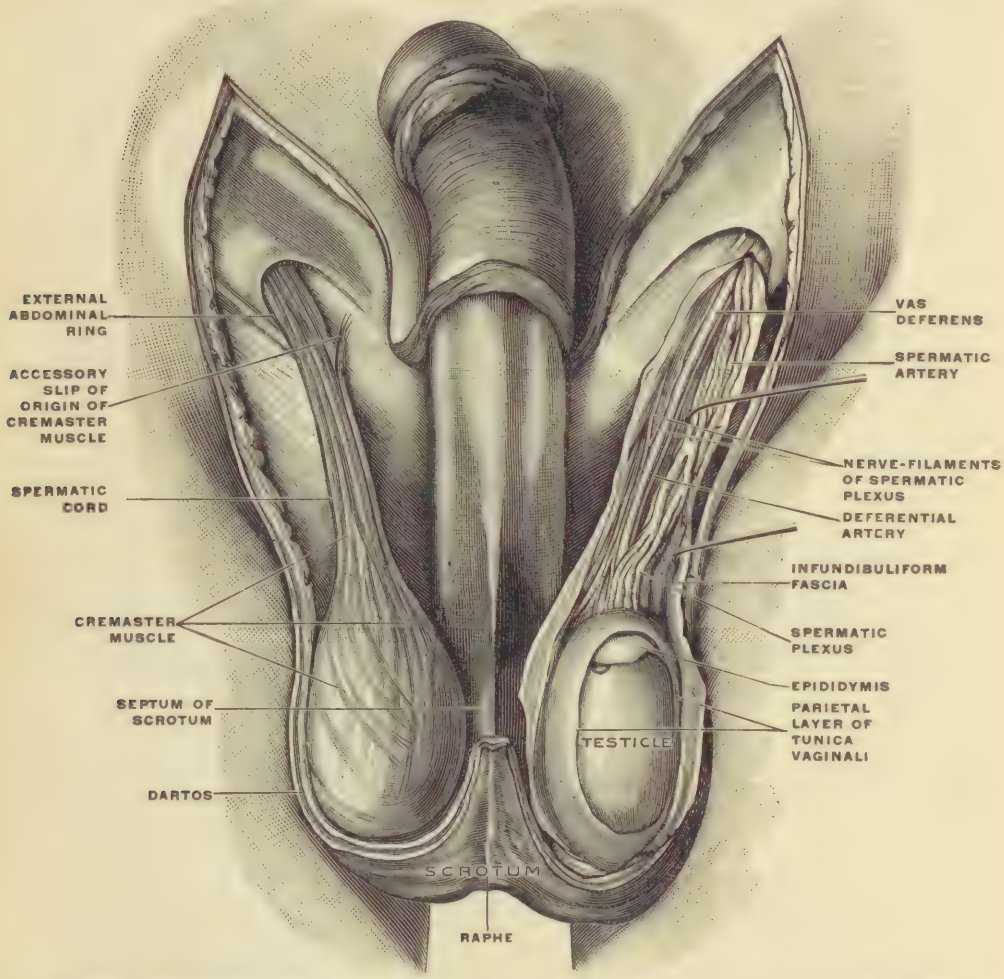

FIG. 1072.—The scrotum. The penis has been turned upward, and the anterior wall of the scrotum has been removed. On the right side, the spermatic cord, the infundibuliform fascia and the Cremaster muscle are displayed; on the left side, the infundibuliform fascia has been divided by a longitudinal incision passing along the front of the cord and the testicle, and a portion of the parietal layer of the tunica vaginalis has been removed to display the testicle and a portion of the head of the epididymis, which are covered by the visceral layer of the tunica vaginalis. (Toldt.)

dartos by loose areolar tissue, which allows of considerable movement of the latter upon it, but is intimately connected with the succeeding layers.

The Cremasteric Fascia (*fascia cremasterica*) (Figs. 1071 and 1072).—The cremasteric fascia consists of scattered bundles of muscular fibres, the **Cremaster muscle** (*m. cremaster*) (Figs. 1071 and 1072) connected together into a continuous covering by intermediate areolar tissue. The muscular fibres are continuous with the lower border of the Internal oblique muscle.

The Infundibuliform Fascia (*tunica vaginalis communis* [*testis et funiculi spermatici*]) (Figs. 1071 and 1071).—The infundibuliform fascia is a thin membranous

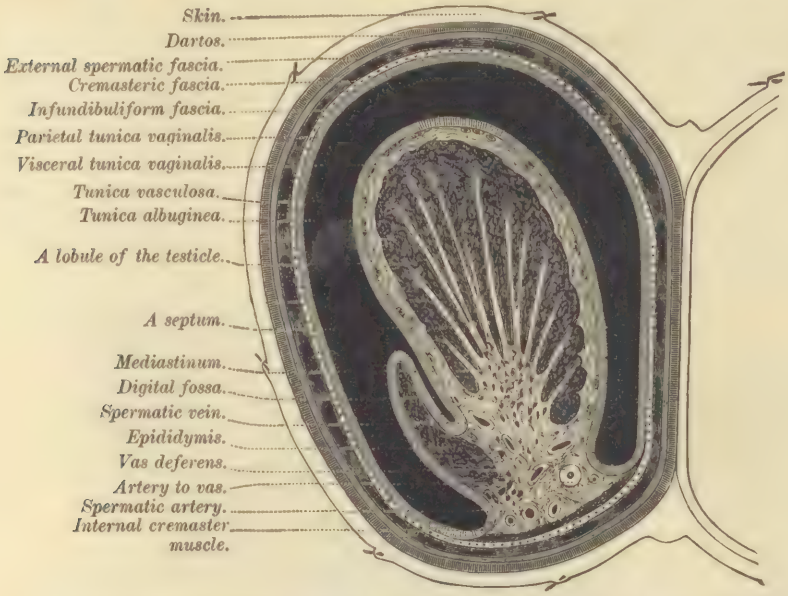

FIG. 1073.—Transverse section through the left side of the scrotum and the left testicle. The sac of the tunica vaginalis is represented in a distended condition. (Delépine.)

layer, which loosely invests the surface of the cord. It is a continuation downward of the fascia transversalis. Beneath it is a quantity of loose connective tissue which connects this layer of fascia with the spermatic cord and posterior parts of the tes-

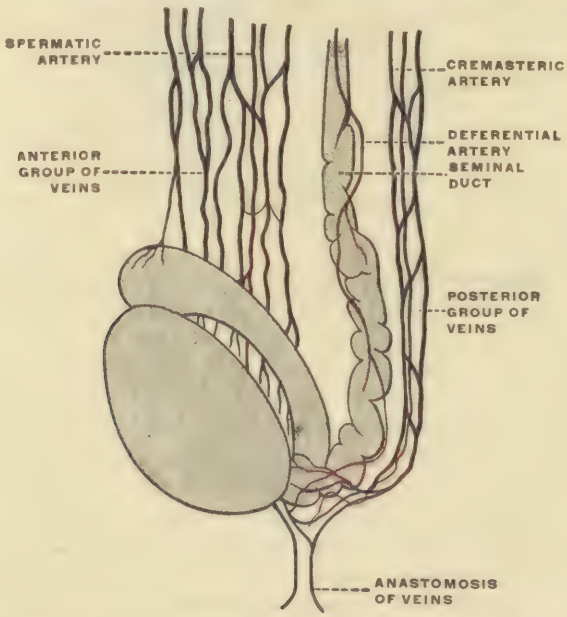

FIG. 1074.—The arteries of the testicle and the cord. (Poirier and Charpy.)

ticle. This connective tissue is continuous above with the subserous areolar tissue of the abdomen. These two layers, the infundibuliform fascia and the tissue beneath

it, are known collectively as the **fascia propria.** The infundibuliform fascia completely encloses the testicle and epididymis and is fused with the parietal lamina of the tunica vaginalis propria testis.

The Tunica Vaginalis (*tunica vaginalis propria testis*).—The tunica vaginalis is described with the testis (p. 1469.)

Vessels and Nerves.—The **arteries** supplying the coverings of the testis are: the superficial and deep external pudic, from the femoral; the superficial perineal branch of the internal pudic; and the cremasteric branch from the deep epigastric. The **veins** follow the course of the corresponding arteries. The **lymphatics** terminate in the inguinal glands. The **nerves** are: the ilio-inguinal branch of the lumbar plexus, the two superficial perineal branches of the internal pudic nerve, the inferior pudenal branch of the small sciatic nerve, and the genital branch of the genito-crural nerve.

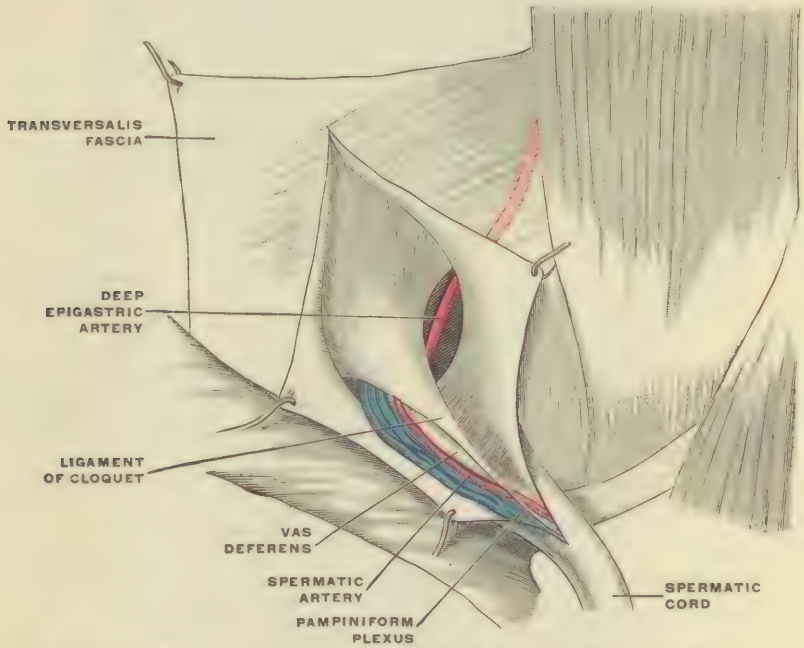

FIG. 1075.—The spermatic cord and the ligament of Cloquet. (Poirier and Charpy.)

THE SPERMATIC CORD (FUNICULUS SPERMATICUS) (Figs. 1071, 1072, 1075, 1076).

The spermatic cord extends from the internal abdominal ring, where the structures of which it is composed converge, to the back part of the testicle. In the abdominal wall the cord passes obliquely along the inguinal canal, lying at first beneath the Internal oblique muscle and upon the fascia transversalis; but nearer the pubes it rests upon Poupart's ligament, having the aponeurosis of the External oblique in front of it and the conjoined tendon behind it. It then escapes at the external ring, and descends nearly vertically into the scrotum. The left cord is usually rather longer than the right, consequently the left testis generally hangs somewhat lower than its fellow.

Structure.—The spermatic cord contains the spermatic duct, the deferential artery and veins, the spermatic artery, the pampiniform plexus of veins, the spermatic plexus, and the deferential plexus of the sympathetic nerve, lymphatics, and the cord-like remnant of the funicular process of peritoneum called the **ligament**

of Cloquet (Fig. 1075). All the above structures are held together by connective tissue. These structures are ensheathed by the **infundibuliform process of the transversalis fascia** (*tunica vaginalis communis* [*testis et funiculi spermatici*]) (Fig. 1075 and p. 1064). This fascia is thin above and thicker below, and encloses the testicle and epididymis, as well as the cord, being firmly adherent to the parietal layer of the **vaginal tunic of the testicle** and with the posterior portion of the testicle and epididymis. Upon this fascia are the fibres of the Cremaster muscle, which spring from the internal oblique, and in this fascia are the cremasteric artery, the genital branch of the genito-crural nerve, and external spermatic veins. This fascia is surrounded by the **intercolumnar** or **spermatic fascia** (*fascia cremasterica* [*Cooperi*]), which is distinct above, but not below.

Vessels and Nerves of the Spermatic Cord.—The **arteries** (Figs. 1074 and 1080) of the cord are: the spermatic, from the aorta; the artery of the vas deferens, from the superior vesical; the cremasteric, from the deep epigastric.

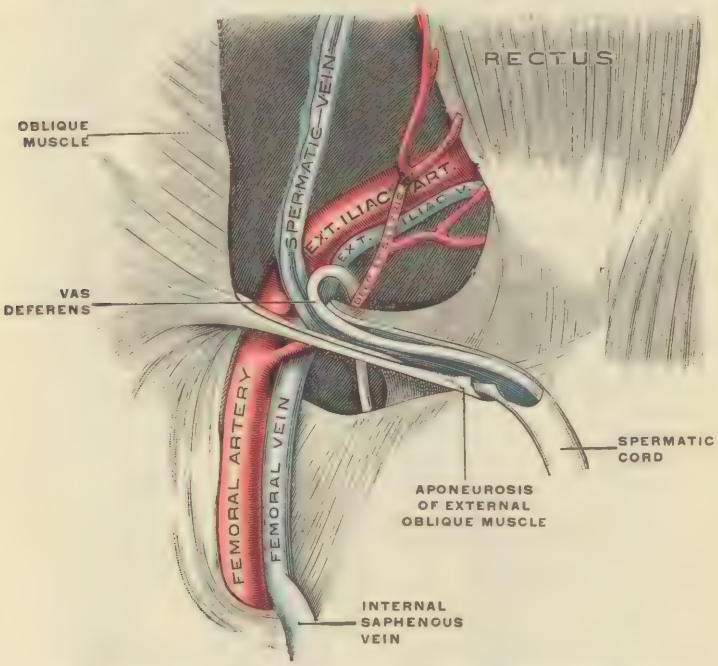

Fig. 1076.—The spermatic cord in the inguinal canal. (Poirier and Charpy.)

The **spermatic artery** (*a. spermatica interna*) arises from the abdominal aorta below the renal artery, descends by the Psoas muscle, crosses the ureter and external iliac vessels, meets the vas deferens at the internal abdominal ring, escapes from the abdomen at the internal or deep abdominal ring, and lying in front of the vas deferens accompanies the other constituents of the spermatic cord along the inguinal canal and through the external abdominal ring into the scrotum. It then descends to the testicle, and, becoming tortuous, divides into several branches, two or three of which, the **epididymal branches**, accompany the vas deferens and supply the epididymis, anastomosing with the artery of the vas deferens and the cremasteric artery; others, the **glandular branches**, pierce the back of the tunica albuginea and supply the substance of the testis.

The **artery of the vas deferens**, a branch of the superior vesical, is a long slender vessel which accompanies the vas deferens, ramifying upon the coats of that duct, and anastomosing with the spermatic artery and the cremasteric artery near the testis.

The **cremasteric artery** (*a. spermatica externa*) is a branch of the deep epigastric artery. It accompanies the spermatic cord and supplies the Cremaster muscle and other coverings of the cord, anastomosing with the spermatic and deferential arteries.

The **spermatic veins** (Figs. 1074, 1075, 1076, and 1077) emerge from the back of the testis and receive tributaries from the epididymis; they unite and form a convoluted plexus, the **pampiniform plexus** (*plexus pampiniformis*), which forms the chief mass of the cord; the vessels composing this plexus are very numerous, and ascend along the cord in front of the vas deferens; below the external or superficial abdominal ring they unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the internal or deep abdominal ring, coalesce to form two veins. These again unite to form a single vein, which opens on the right side into the inferior vena cava at an acute angle, and on the left side into the renal vein at a right angle.

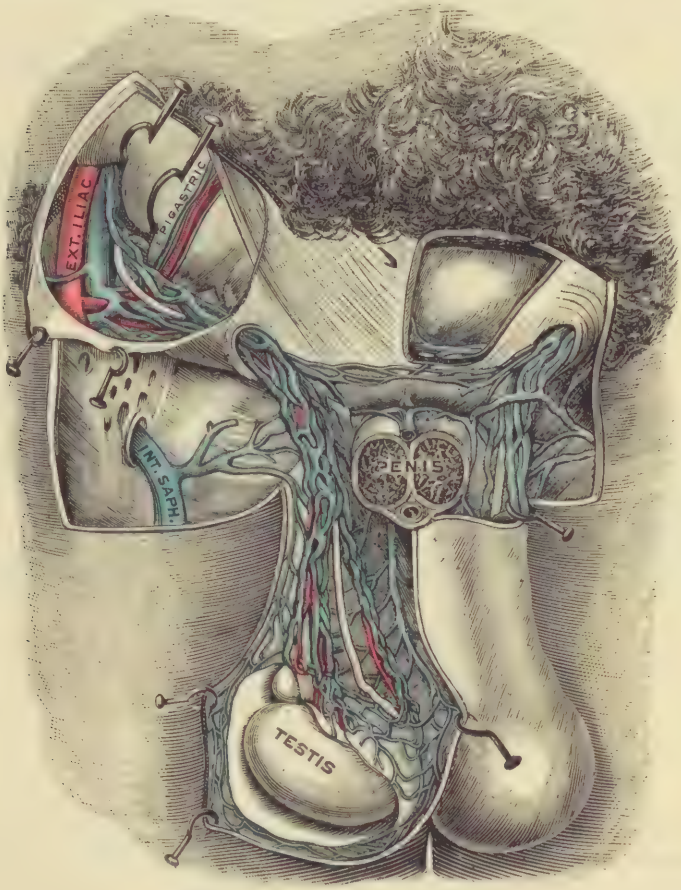

FIG. 1077.—Spermatic veins. (Testut.)

The **lymphatic vessels** of the scrotum terminate in the superficial inguinal glands. The lymphatics of the testicle join the lymphatics of the epididymis and of the visceral layer of the vaginal tunic of the testicle, and ascend in the spermatic cord. They reach the lumbar region along the spermatic blood-vessels and terminate in the **juxta-aorta glands**, and sometimes in the glands in front of the aorta. The lymphatics of the seminal duct pass to the **external iliac glands**.

The **nerves** are the **spermatic plexus** from the sympathetic, joined by filaments from the **pelvic plexus** which accompany the artery of the vas deferens.

The Ligament of the Scrotum.—See Fig. 1070 and p. 1462.

Surgical Anatomy.—The scrotum forms an admirable covering for the protection of the testicle. This body, lying suspended and loose in the cavity of the scrotum, and surrounded by a serous membrane, is capable of great mobility, and can therefore easily slip about within the scrotum, and thus avoid injuries from blows or squeezes. The skin of the scrotum is very elastic and capable of great distention, and on account of the looseness and amount of subcutaneous tissue the scrotum becomes greatly enlarged in cases of *œdema*, to which this part is especially liable on account of its dependent position. The scrotum is frequently the seat of *epithelioma;* this is no doubt due to the rugæ on its surface, which favor the lodgement of dirt, and this, causing irritation, is the exciting cause of the disease. Cancer was especially common in chimney-sweeps from the lodgement of soot. The scrotum is also the part most frequently affected by *elephantiasis*.

On account of the looseness of the subcutaneous tissue considerable *extravasations of blood* may take place from very slight injuries. It is therefore generally recommended never to apply leeches to the scrotum, since they may lead to considerable ecchymosis, but rather to puncture one or more of the superficial veins of the scrotum in cases where local bloodletting from this part is judged to be desirable. The muscular fibre in the dartos causes contraction and considerable diminution in the size of a *wound of the scrotum*, as after the operation of castration, and is of assistance in keeping the edges together and covering the exposed parts.

THE TESTICLES (TESTES) (Figs. 1069, 1071, 1072, 1078, 1079).

The testicles are suspended in the scrotum by the spermatic cords. As the left spermatic cord is rather longer than the right one, the left testicle hangs somewhat lower than its fellow. Each gland is of an oval form, compressed laterally, and having an oblique position in the scrotum, the **upper extremity** (*extremitas superior*) being directed forward and a little outward, the **lower extremity** (*extremitas inferior*), backward and a little inward; the **anterior convex border** (*margo anterior*) looks forward and downward; the **posterior** or **straight border** (*margo posterior*), to which the cord is attached, backward and upward.

The **anterior border** and **lateral surfaces** (*facies lateralis et facies medialis*), as well as both extremities of the organ, are convex, free, smooth, and invested by the visceral layer of the tunica vaginalis. The posterior border, to which the cord is attached, receives only a partial investment from that membrane. Lying upon the outer edge of this posterior border is a long, narrow, flattened body, named, from its relation to the testis, the **epididymis** (*διδυμος, testis*) (Figs. 1078 and 1079). The curve of the epididymis is convex outward and backward. It consists of a **central portion** or **body** (*corpus epididymidis*); an upper enlarged extremity, the **head** or **globus major** (*caput epididymidis*); and a lower pointed extremity, the **tail** or **globus minor** (*cauda epididymidis*). The globus major is directed inward and is intimately connected with the upper end of the testicle by means of its efferent ducts, and the globus minor is connected with its lower end by cellular tissue and a reflection of the tunica vaginalis. The globus minor bends suddenly and passes into the **seminal duct**, the direction of which is upward and backward. The outer surface and upper and lower ends of the epididymis are free and covered by serous membrane; the body is also completely invested by it, excepting along its posterior border, and between the body and the testicle is a pouch or *cul-de-sac*, named the **digital fossa** (*sinus epididymidis*). Above this fossa is a fold of the tunica vaginalis, which is called the **ligamentum epididymidis superior**, and below it is another fold, the **ligamentum epididymidis inferior**. The epididymis is connected to the back of the testis by a fold of the serous membrane. Attached to the upper end of the testis, close to the globus major, is a small body. It is oblong in shape and has a broad base. Attached to the globus major of the epididymis is another small body, which is pear-shaped and has a stalk. These bodies are

believed to be the remains of the upper extremity of the Müllerian duct, and are termed the **hydatids of Morgagni**; some observers, however, regard the stalked hydatid as being a rudiment of the pronephros. The body with a broad base is the **non-pedunculated hydatid** (*appendix testis* [*Morgagnii*]) (Figs. 1071 and 1078);

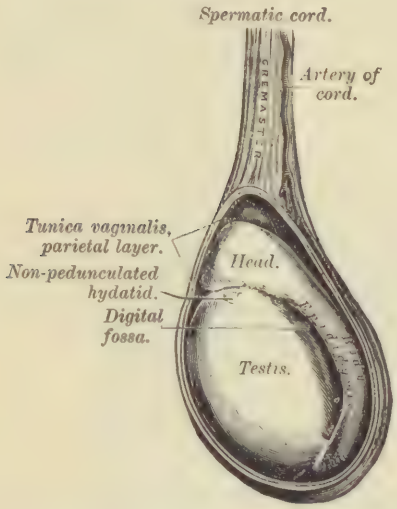

FIG. 1078.—The testis *in situ*, the tunica vaginalis having been laid open.

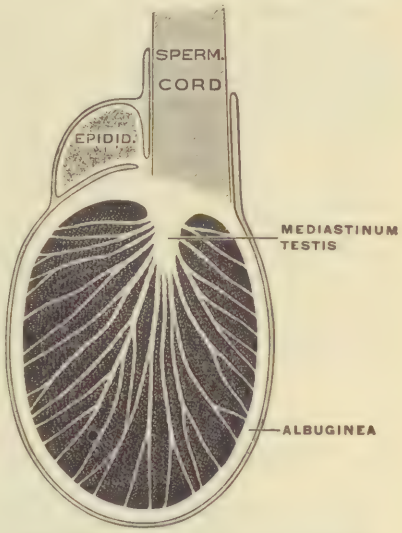

FIG. 1079.—Frontal section of the testicle and epididymis. (Poirier and Charpy.)

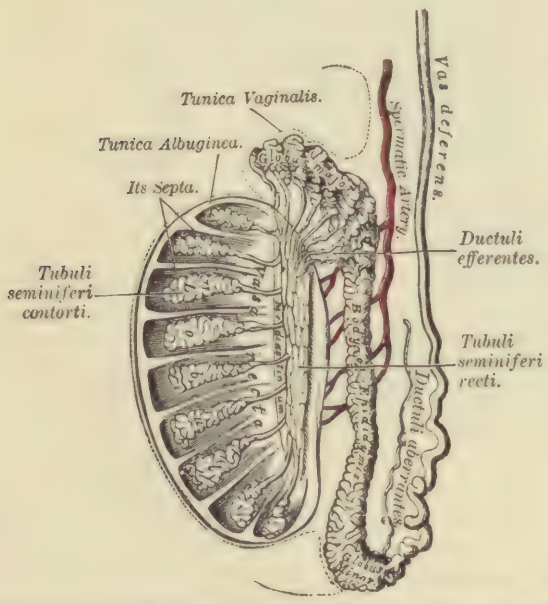

FIG. 1080.—Vertical section of the testicle, to show the arrangement of the ducts.

the pear-shaped body is the **pedunculated hydatid** (*appendix epididymidis*). When the testicle is removed from the body, the position of the vas deferens, on the posterior surface of the testicle and inner side of the epididymis, marks the side to which the gland has belonged.

Size and Weight.—The average dimensions of this gland are from one and a half to two inches in length, one inch in breadth, and an inch and a quarter in the antero-posterior diameter, and the weight varies from six to eight drachms, the left testicle being a little the larger.

The Tunics of the Testicle.—The testis is invested by three tunics—the **tunica vaginalis, tunica albuginea,** and **tunica vasculosa.**

The **Proper Sheath of the Testicle** or the **Tunica Vaginalis** (*tunica vaginalis propria testis*) (Figs. 1069, 1071, 1072, 1073, and 1080) is the serous covering of the testicle and epididymis. It is a pouch of serous membrane, derived from the peritoneum (*processus vaginalis peritonaei*) during the descent of the testis in the fœtus from the abdomen into the scrotum. After its descent that portion of the pouch which

extends from the internal ring to near the upper part of the gland, the **funicular process**, becomes obliterated, the lower portion remaining as a shut sac (*tunica vaginalis propria testis*), which invests the outer surface of the testis, and is reflected on to the internal surface of the scrotum; hence it may be described as consisting of a visceral and parietal portion.

The **Visceral Portion** (*lamina visceralis*) of the tunica vaginalis propria covers the outer surface of the testis, as well as the epididymis, connecting the latter to the testis by means of a distinct fold. From the posterior border of the gland it is reflected on to the internal surface of the infundibuliform process of the transversalis fascia, and between the tunic and the fascia is a layer of unstriated muscle fibres, the **Internal cremaster muscle** (Fig. 1073).

The **Parietal Portion** (*lamina parietalis*) of the tunica vaginalis propria is the reflected portion. It is far more extensive than the visceral portion, extending upward for some distance in front and on the inner side of the cord, and reaching below the testis. The inner surface of the tunica vaginalis is free, smooth, and covered by a layer of endothelial cells. The interval between the visceral and parietal layers of this membrane constitutes the **cavity of the tunica vaginalis** and contains a small amount of serous fluid.

The obliterated portion of the pouch may generally be seen as a fibro-cellular thread, the **ligament of Cloquet** (*rudimentum processus vaginalis*) (Fig. 1075), lying in the loose areolar tissue around the spermatic cord; sometimes this may be traced as a distinct band from the upper end of the inguinal canal, where it is connected with the peritoneum, down to the tunica vaginalis; sometimes it gradually becomes lost on the spermatic cord. Occasionally no trace of it can be detected. In some cases it happens that the pouch of peritoneum does not become obliterated, but the sac of the peritoneum communicates with the tunica vaginalis. This may give rise to one of the varieties of oblique inguinal hernia; or in other cases the pouch may contract, but not become entirely obliterated; it then forms a minute canal leading from the peritoneum to the tunica vaginalis.[1]

The Tunica Albuginea (Figs. 1073, 1079, and 1080).—The tunica albuginea is the fibrous covering of the testis. It is a dense fibrous membrane, of a bluish-white color, composed of bundles of white fibrous tissue, which interlace in every direction. Its outer surface is covered by the tunica vaginalis, except at the points of attachment of the epididymis to the testicle, and along its posterior border, where the spermatic vessels enter the gland. This membrane surrounds the glandular structure of the testicle, and at its posterior border forms a projection, triangular in shape and cellular in structure, which is reflected into the interior of the gland, forming an incomplete vertical septum, called the **mediastinum testis**.

The **Mediastinum Testis** (*corpus Highmori*) (Figs. 1073, 1079, and 1080) extends from the upper, nearly to the lower, extremity of the gland, and is wider above than below. From the front and sides of this septum numerous slender fibrous cords and imperfect septa, called the **trabeculae** (*septula testis*) (Fig. 1080), are given off, which radiate toward the surface of the organ, and are attached to the inner surface of the tunica albuginea. This scaffolding of connective tissue divides the **parenchyma** (*parenchyma testis*) of the organ into a number of incomplete spaces, which are somewhat cone-shaped, being broad at their bases at the surface of the gland, and becoming narrower as they converge to the mediastinum. The mediastinum supports the blood-vessels, lymphatics, and ducts of the testis in their passage to and from the substance of the gland, and contains numerous fine canals, into which open the very small tubules of the proper substance of the testicle.

[1] It is recorded that in the post-mortem examination of Sir Astley Cooper a minute funicular canal was found on each side of the body. Sir Astley Cooper states that when a student he suffered from inguinal hernia; probably this was of the congenital variety, and the canal found after death was the remains of the one down which the hernia travelled (Lancet, 1824, vol. ii. p. 116.).—Ed. of 15th English edition.

The Tunica Vasculosa (Fig. 1073).—The tunica vasculosa is the vascular layer of the testis, and consists of a plexus of blood-vessels held together by a delicate areolar tissue. It covers the inner surface of the tunica albuginea and the different septa in the interior of the gland, and therefore forms an internal investment to all the spaces of which the gland is composed.

Structure of the Testicle and Epididymis (Fig. 1080).—The glandular structure of the testis consists of numerous **lobules** (*lobuli testis*). Their number, in a single testis, is estimated by Berres at 250, and by Krause at 400. They differ in size according to their position, those in the middle of the gland being larger and longer. The lobules are conical in shape, the base of each being directed toward the circumference of the organ, the apex toward the mediastinum. Each lobule is contained in one of the intervals between the fibrous cords and vascular processes which extend between the mediastinum testis and the tunica albuginea, and consists of from one to three or more minute convoluted tubes, which anastomose with each other, the **tubuli seminiferi contorti.** The contorted tubes unite at the apex of the lobules and form the **straight tubes** (*tubuli seminiferi recti*). The straight tubes pass into the mediastinum testis and form the network known as the **rete testis of Haller** (Fig. 1080). The rete testis is lined with flattened epithelium. The tubes are lined with columnar ciliated epithelium. The **efferent ducts** (*ducti efferentes testis*) (Fig. 1080), about twelve to fifteen in number, arise from the rete. The contorted tubes may be separately unravelled by careful dissection under water, and may be seen to commence either by free cæcal ends or by anastomotic loops. The total number of tubes is considered by Munro to be about 300 and the length of each about sixteen feet; by Lauth their number is estimated at 840, and their average length two feet and a quarter. The diameter varies from $\frac{1}{200}$ to $\frac{1}{150}$ of an inch. The tubuli are pale in color in early life, but in old age they acquire a deep-yellow tinge from containing much fatty matter. Each tube consists of a basement layer, formed of epithelioid cells united edge to edge, outside of which are other layers of flattened cells arranged in interrupted laminæ, which give to the tube an appearance of striation in cross-section. The cells of the outer layers gradually pass into the interstitial tissue. Within the basement-membrane are epithelial cells arranged in several irregular layers, which are not always clearly separated, but which may be arranged in three different groups. Among these cells may be seen the **spermatozoids** in different stages of development. 1. Lining the basement-membrane and forming the outer zone is a layer of cubical cells, with small nuclei; these are known as the **lining cells** or **spermatogonia.** The nucleus of some of them may be seen to be in the process of indirect division (*karyokinesis*), and in consequence of this daughter cells are formed, which constitute the second zone. 2. Within this first layer is to be seen a number of larger cells with clear nuclei, arranged in two or three layers; these are the **intermediate cells** or **spermatocytes.** Most of these cells are in a condition of karyokinetic division, and the cells which result from this division form those of the next layer, the **spermatoblasts** or **spermatids.** 3. The third layer of cells therefore consists of the spermatoblasts or spermatids, and each of these, without further subdivision, becomes a **spermatozoid.** They are ill-defined granular masses of protoplasm, of an elongated form, with a nucleus which becomes the head of the future spermatozoid. In addition to these three layers of cells others are seen, which are termed the **supporting cells,** or **cells of Sertoli.** They are elongated and columnar, and project inward from the basement-membrane toward the lumen of the tube. They give off numerous lateral branches, which form a reticulum for the support of the three groups of cells just described. As development of the spermatozoids proceeds the latter group themselves around the inner extremities of the supporting cells. The nuclear part of the spermatozoid, which is partly embedded in the supporting cell, is differentiated to form the head of the spermatozoid, while the cell protoplasm becomes lengthened out to

form the middle piece and tail, the latter projecting into the lumen of the tube. Ultimately the heads are separated and the spermatozoids are set free.

Spermatogenesis.—The stages in the development of the spermatozoids are as follows: The spermatogonia become enlarged to form the spermatocytes, and each spermatocyte subdivides into two cells, and each of these again divides into two spermatids or young spermatozoids, so that the spermatocyte gives origin to four spermatozoids.

The process of spermatogenesis bears a close relation to that of maturation of the ovum. The spermatocyte is equivalent to the immature ovum. It undergoes subdivision, and ultimately gives origin to four spermatozoids, each of which contains, therefore, only one-fourth of the chromatin elements of the nucleus of the spermatocyte. In the process of maturation of the ovum its nucleus divides, one-half being extended as the first polar body. The remaining half of the nucleus again subdivides, one-half being extended as the second polar body. The portion of the nucleus which is retained to form the female pronucleus of the now matured ovum contains, therefore, only one-fourth of the chromatin elements of the original nucleus, and thus the spermatozoid and the matured ovum, so far as their nuclear elements are concerned, may be regarded as of the same morphological value.

The tubules are enclosed in a delicate plexus of capillary vessels, and are held together by an intertubular connective tissue, which presents large interstitial spaces lined by endothelium, which are believed to be the rootlets of lymphatic vessels of the testis.

The **Aberrant Ducts of the Epididymis** (*ductuli aberrantes*) are tortuous and end in blind extremities. The **superior aberrant duct** (*ductus aberrans superior*) is in the globus major and joins the rete testis. The **inferior aberrant duct** (*ductus aberrans inferior*) (Fig. 1080) is in the tail of the epididymis, and takes origin from the duct of the epididymis or the seminal duct. It is a persistent canal of the Wolffian body. It extends up the cord for two or three inches and terminates by a blind extremity, which is occasionally bifurcated. It may be as much as fourteen inches in length. Its structure is similar to that of the seminal duct.

The Seminal Duct or Vas Deferens (*ductus deferens*) (Figs. 1074, 1075, 1076, 1080, 1081, and 1118).—The seminal duct or vas deferens, the excretory duct of the testis, is the continuation of the epididymis. Commencing at the lower part of the globus minor, it ascends along the posterior border of the testis and inner side of the epididymis, and along the back part of the spermatic cord, through the inguinal canal to the internal or deep abdominal ring. From the ring it curves around the outer side of the internal epigastric artery and vein, crosses the external iliac vessels, and descends into the pelvis at the side of the bladder; it arches backward and downward to its base, crossing over the obliterated hypogastric artery and to the inner side of the ureter. At the base of the bladder it lies between that viscus and the rectum, running along the inner border of the seminal vesicle. Behind the bladder it becomes enlarged and sacculated, forming the **ampulla** (*ampulla ductus deferentis*) (Fig. 1081), and then, becoming narrowed at the base of the prostate, unites with the duct of the seminal vesicle to form the **ejaculatory duct** (Fig. 1082). From the internal abdominal ring to the middle of the ampulla the seminal duct is beneath the peritoneum. The vas deferens offers a hard and cord-like sensation to the fingers; it is about two feet in length, of cylindrical form, and about a line and a quarter in diameter. Its walls are dense, measuring one-third of a line, and its canal is extremely small, measuring about half a line.

Structure.—The vas deferens consists of three coats: 1. An **external** or **areolar coat** (*tunica adventitia*). 2. A **muscular coat** (*tunica muscularis*), which in the greater part of the tube consists of two layers of unstriped muscular fibre: an inner layer of thin longitudinal fibres (*stratum internum*), existing only at the beginning,

a thick layer of circular fibres (*stratum medium*), and a thick external layer of longitudinal fibres (*stratum externum*). 3. An **internal** or **mucous coat** (*tunica mucosa*), which is pale, and arranged in longitudinal folds; its epithelial cells are of the columnar variety.

Organ of Giraldes (*paradidymis*).—This term is applied to a small body of rounded shape in the lower end of the spermatic cord, in front of the blood-vessels. It consists of a small collection of minute vesicles and a small collection of convoluted tubules. These tubes are lined with columnar ciliated epithelium, and probably represents the remains of a part of the Wolffian body.

Surgical Anatomy.—Abnormalities in the descent and position of the testicle have been discussed (p. 1462). The testicle may require removal for *malignant disease*, *tuberculous disease*, *cystic disease*, in cases of large *hernia testis*, and in some instances of *incompletely descended* or *misplaced testicles*. The operation of double *castration* has also been, during the last few years, performed for enlargement of the prostate gland; for it has been found that removal of the testicles is followed by very rapid and often considerable diminution in the size of the prostate. The operation is, however, one of severity, and is frequently followed by death in these cases, performed, as it necessarily is, in old men. Reginald Harrison has proposed to substitute for it excision of a portion of each vas deferens (*vasectomy*). The *operation of castration* is a comparatively simple one. An incision is made into the cavity of the tunica vaginalis from the external ring to the bottom of the scrotum. The coverings are shelled off the organ, and the mesorchium, stretching between the back of the testicle and the scrotum, divided. The cord is then isolated, and an aneurism needle, armed with a double ligature, passed under it, as high as is thought necessary, and the cord tied in two places, and divided between the ligatures. Sometimes, in cases of malignant disease, it is desirable to open the inguinal canal and tie the cord as near the internal abdominal ring as possible.

A collection of serous fluid in the sac of the vaginal tunic of the testicle is known as an *ordinary* or *testicular hydrocele*. In *congenital hydrocele* a communication remains between the tunica vaginalis testis and the peritoneal cavity. This communication should have closed during development. In *infantile hydrocele* the tunica vaginalis and part of the funicular process are distended with fluid, but the funicular process is closed above and the cavity of the hydrocele does not communicate with the peritoneal cavity. In *encysted hydrocele of the cord* the funicular process is closed above and below, but between these points is not obliterated. In *funicular hydrocele* the funicular process is closed below and open above. Congenital hydrocele can usually be cured by the application of a truss. This obliterates the upper end of the funicular process, and the obliteration once begun may proceed to completion. If it does not, the condition has become an infantile hydrocele. An infantile hydrocele can usually be cured by multiple punctures or tapping. The same is true of encysted hydrocele of the cord. In hydrocele of the funicular process wear a truss for a time and then tap. In ordinary testicular hydrocele incise and pack, or incise and suture, the cut edge of the parietal layer of the tunic to the skin, or extirpate the parietal layer of the tunic. A successful method is that of Longuet. He makes an incision, pulls out the testicle, and allows all the coats except the skin to fall behind and make a sheath for the cord. These coats are held behind by one catgut suture. A bed is made for the testicle beneath the skin toward the septum of the scrotum. The testicle is rotated on its long axis and placed in the bed, and the skin is sutured above it. This operation is known as *extraserous transposition*. If a portion of bowel enters an open vaginal process the condition is *congenital hernia*.

In *infantile hernia* the funicular process is closed above but not below, and the hernia descends in a special sac back of the vaginal tunic. If the hernia pushes down on the vaginal process and causes it to double on itself the condition is *encysted infantile hernia*.

The Semen and the Spermatozoids.—Semen consists of spermatozoids with liquids and solids. Part of the semen comes from the testicles, most of it from accessory glands—that is, from the glands of the seminal ducts, the seminal vesicles, the prostate gland, and Cowper's glands. Semen is a viscid, whitish fluid, of alkaline reaction and characteristic odor. It contains water and about 18 per cent. of solid matter. In this solid matter are fat, cholesterin, lecithin, proteids, nuclein, xanthin, chlorides, sulphates, and phosphates of sodium and potassium. Böttcher's crystals, which can be obtained from semen, are composed of phosphate of spermine. Spermine is a nitrogenous substance. The fluid portion of semen carries and probably nourishes the living cells known as spermatozoids.

The spermatozoids (Fig. 1081) are minute, thread-like bodies, which constitute the essential elements of the semen. Each consists of a **head**, a middle piece or **body**, and an elongated filament or **tail**. The head, on surface view, appears oval in shape, but if seen in profile it is narrow and pointed at its free end. It represents the modified nucleus of the spermatid, and consists chiefly of chromatin, and so stains readily with nuclear reagents; it is covered by a thin cap of protoplasm. The body is a short cylindrical or conical piece, intervening between the head and tail, and is therefore sometimes spoken of as the intermediate segment. The tail is about four times the combined lengths of the head and body; its terminal part is extremely fine, and is named the **end-piece**. Contained within the body and tail is an axial filament, surrounded, except in the end-piece, by a thin layer of protoplasm; this axial filament terminates just below the head in a rounded knob or button. In virtue of their tails, which act as propellers, the spermatozoids, in the fresh condition, are capable of free movement, and if placed in favorable surroundings (*e. g.*, in the female passages) may retain their vitality for some days or even weeks.

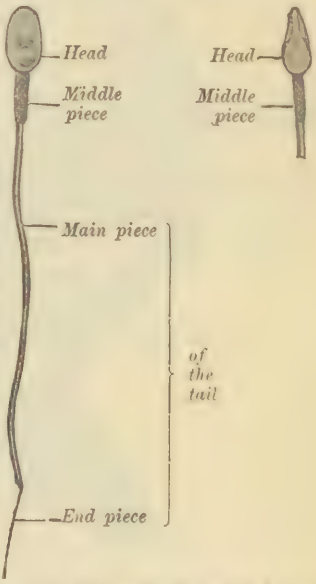

FIG. 1081.—Spermatozoid of man. At the left a surface view is shown; at the right a lateral view. × 1200. (Szymonowicz, after Retzius.)

THE SEMINAL VESICLES (VESICULAE SEMINALES) (Figs. 1082, 1083).

The seminal vesicles are two lobulated membranous pouches placed between the base of the bladder and the rectum, serving as reservoirs for the semen, and secreting a fluid to be added to the secretion of the testicles. Each sac is somewhat pyramidal in form, the broad end being directed backward and the narrow end forward toward the prostate. It measures about two and a half inches in length, about five lines in breadth, and two or three lines in thickness. They vary, however, in size, not only in different individuals, but also in the same individual on the two sides. The *upper surface* is in contact with the base of the bladder, extending from near the termination of the ureters to the base of the prostate gland. The *under surface* rests upon the rectum, from which it is separated by the recto-vesical fascia. Their *posterior extremities* diverge from each other. Their *anterior extremities* are pointed, and converge toward the base of the prostate gland, where each joins with the corresponding seminal duct to form the ejaculatory duct. Along the inner margin of each vesicle runs the enlarged and convoluted vas deferens. The inner border of the vesicle and the corresponding seminal duct form the lateral boundaries of a triangular space, limited behind by the recto-vesical peritoneal fold; the portion of the bladder included in this space rests on the rectum.

Each vesicle consists of a single tube, coiled upon itself and giving off several irregular caecal diverticula (Fig. 1082), the separate coils, as well as the diverticula, being connected together by fibrous tissue. When uncoiled this tube is about the diameter of a quill, and varies in length from four to six inches; it terminates posteriorly in a *cul-de-sac;* its anterior extremity becomes constricted into a narrow straight duct, the **excretory duct** (*ductus excretorius*) (Fig. 1083), which joins with the corresponding seminal duct, and forms the ejaculatory duct.

The Ejaculatory Ducts (*ductus ejaculatorii*) (Fig. 1083).—The ejaculatory ducts are two in number, one on each side. Each duct is formed by the junction of the duct of the seminal vesicle with the seminal duct. Each duct is about three-quarters of

an inch in length; it commences at the base of the prostate, and runs forward and downward between the middle and lateral lobes of that gland, and along the side of the sinus pocularis, to terminate by a separate slit-like orifice close to or just within the margins of the sinus. The ducts diminish in size and also converge toward their termination.

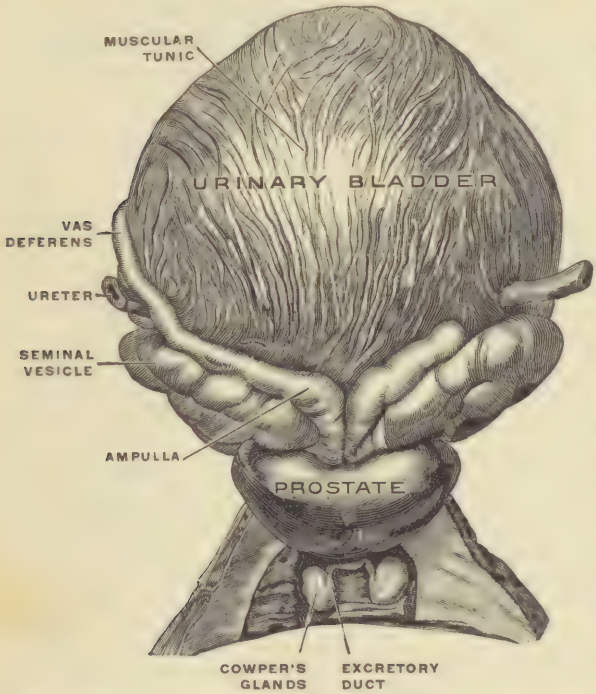

FIG. 1082.—The urinary bladder, distended, with surrounding structures, viewed from behind. (Spalteholz.)

Structure.—The seminal vesicles are composed of three coats: an **external** or **areolar** (*tunica adventitia*); a **middle** or **muscular coat** (*tunica muscularis*), which is thinner than in the seminal duct, and is arranged in two layers, an outer, longitudinal, and inner, circular; an **internal** or **mucous coat** (*tunica mucosa*), which is pale, of a whitish-brown color, and presents a delicate reticular structure, like that seen in the gall-bladder, but the meshes are finer. The epithelium is columnar.

The coats of the ejaculatory ducts are extremely thin. They are: an **outer fibrous layer**, which is almost entirely lost after the entrance of the duct into the prostate; a **layer of muscular fibres**, consisting of an outer thin circular and an inner longitudinal layer; and the **mucous membrane**.

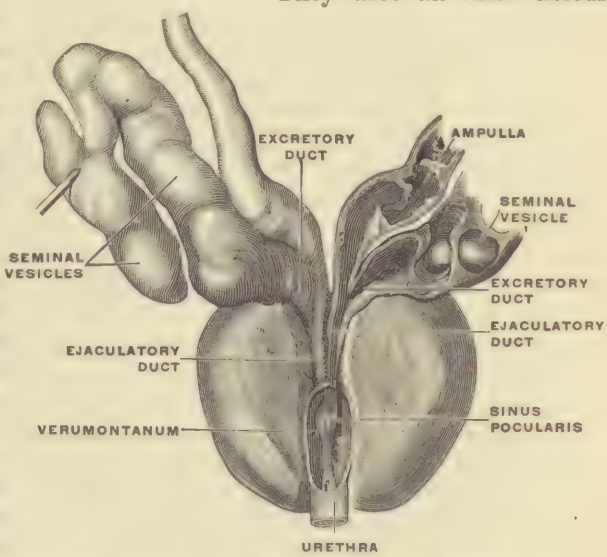

FIG. 1083.—The ejaculatory ducts viewed from in front and above. (Spalteholz.)

Vessels and Nerves.—The **arteries** supplying the vesiculae seminales are derived from the **middle** and **inferior vesical** and **middle haemorrhoidal**. The **veins** and **lymphatics** accompany the arteries. The **lymphatics** anastomose on the surface of the vesicle. The trunks from this network anastomose with the lymphatics of the bladder and prostate, and pass to the **external** and **internal iliac glands**. The **nerves** are derived from the **pelvic plexus**.

Surgical Anatomy.—The vesiculae seminales are often the seat of an extension of the disease in cases of *tuberculosis* of the testicle, and should always be examined through the rectum before coming to a decision with regard to castration in this affection. The vesicles have been deliberately *extirpated* for local tuberculosis. In gonorrhœa the seminal vesicles may become acutely inflamed (*acute seminal vesiculitis*). *Chronic seminal vesiculitis* may follow the acute form or may arise insidiously during gonorrhœa.

THE FEMALE ORGANS OF GENERATION.

EXTERNAL ORGANS (PARTES GENITALES EXTERNAE MULIEBRES).

THE external organs of generation in the female are: the **mons Veneris**, the **labia majora** and **minora**, the **clitoris**, the **meatus urinarius**, and the **orifice of the vagina**. The term **vulva** (*pudendum muliebre*), as generally applied, includes all of these parts.

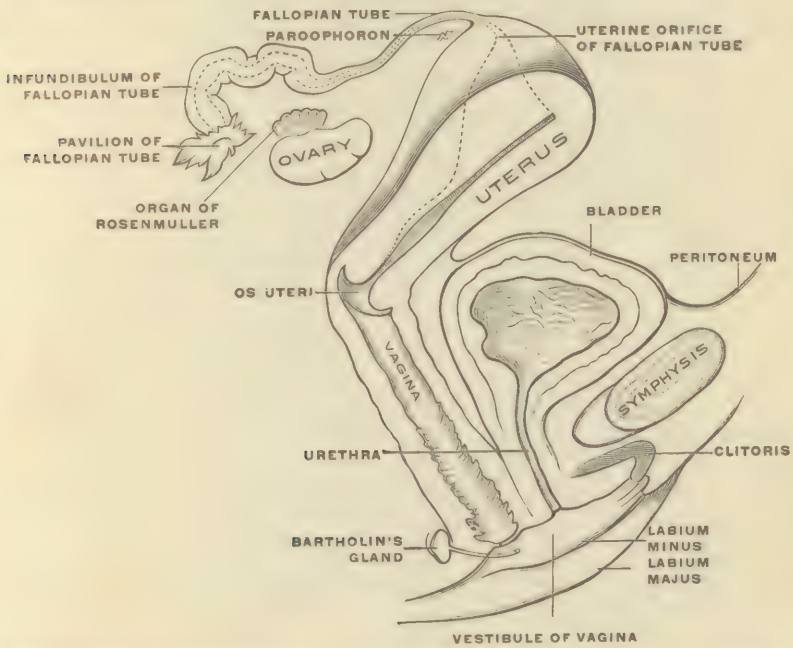

FIG. 1084.—Diagrammatic representation of the female reproductive organs and their relations to the bladder and urethra, lateral view. (Toldt.)

THE MONS VENERIS (MONS PUBIS) (Figs. 1085, 1086).

The mons Veneris is the rounded eminence in front of the pubic symphysis, formed by a collection of fatty tissue beneath the integument. It becomes covered with hair at the time of puberty.

THE LARGE LIPS OR LABIA MAJORA (LABIA MAJORA PUDENDI) (Figs. 1085, 1086, 1087).

The large lips or labia majora are two prominent longitudinal cutaneous folds extending downward from the mons Veneris to the anterior boundary of the perinæum, and enclosing the common urino-sexual opening. Each **labium majus** (*labium majus pudendi*) has two surfaces, an outer, which is pigmented and

covered with strong, crisp hairs; and an inner, which is smooth and is beset with large sebaceous follicles and is continuous with the genito-urinary mucous tract; between the two there is a considerable quantity of areolar tissue, fat, and a tissue resembling the dartos of the scrotum, besides vessels, nerves, and sweat and sebaceous glands. Between the labia majora is the **pudendal slit** (*rima pudendi*). The labia are thicker in front, where they form by their meeting the **anterior commissure** (*commissura labiorum anterior*). Posteriorly they are not really joined, but appear to become lost in the neighboring integument, terminating close to, and nearly parallel with, each other. Together with the connecting skin between them, they form the **posterior commissure** (*commissura labiorum posterior*), or posterior boundary of the vulval orifice. The interval between the posterior

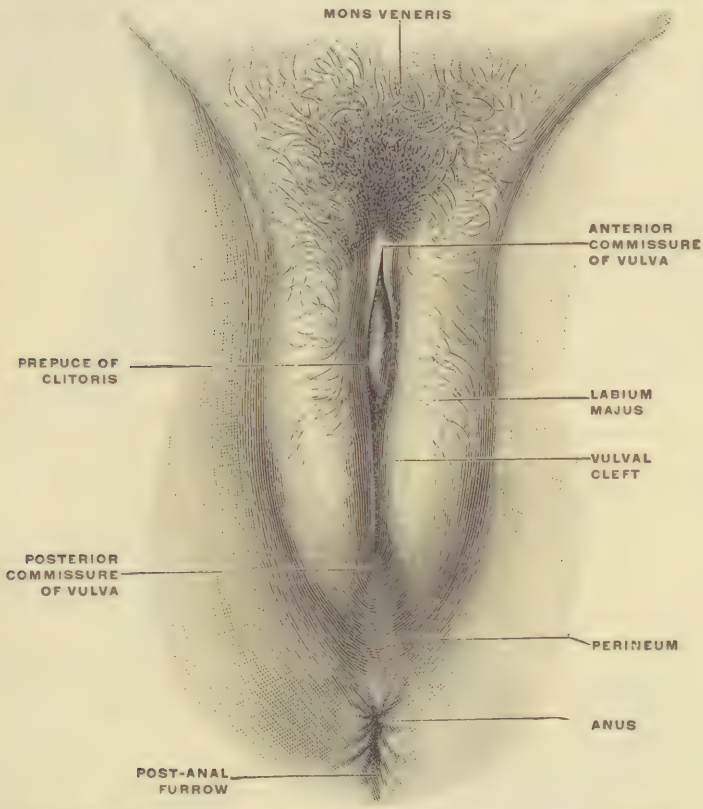

FIG. 1085.—The female pudendum or vulva with the labia majora. (Toldt.)

commissure and the anus, about an inch to an inch and a quarter in length, constitutes the **obstetric perinæum**. The **fourchette** (*frenulum labiorum pudendi*) (Fig. 1086) is the anterior edge of the perinæum, and between it and the hymen is a depression, the **fossa navicularis of the vulva** or the **vestibule of the vagina** (*fossa navicularis vestibuli vaginae*) (Fig. 1086). The labia majora correspond to the scrotum in the male.

THE SMALL LIPS, NYMPHAE OR LABIA MINORA (LABIA MINORA PUDENDI) (Figs. 1085, 1086, 1087).

The small lips are two small cutaneous folds, situated within the labia majora, and extending from the clitoris obliquely downward, outward, and back-

ward for about an inch and a half on each side of the orifice of the vagina, between which and the labia majora they are lost in women who have borne children. In women who have not borne children they unite behind and usually form a fold (*frenulum labiorum pudendi*). Behind this fold is the fossa navicularis. Anteriorly, each lip divides into two limbs. The external limbs unite over the

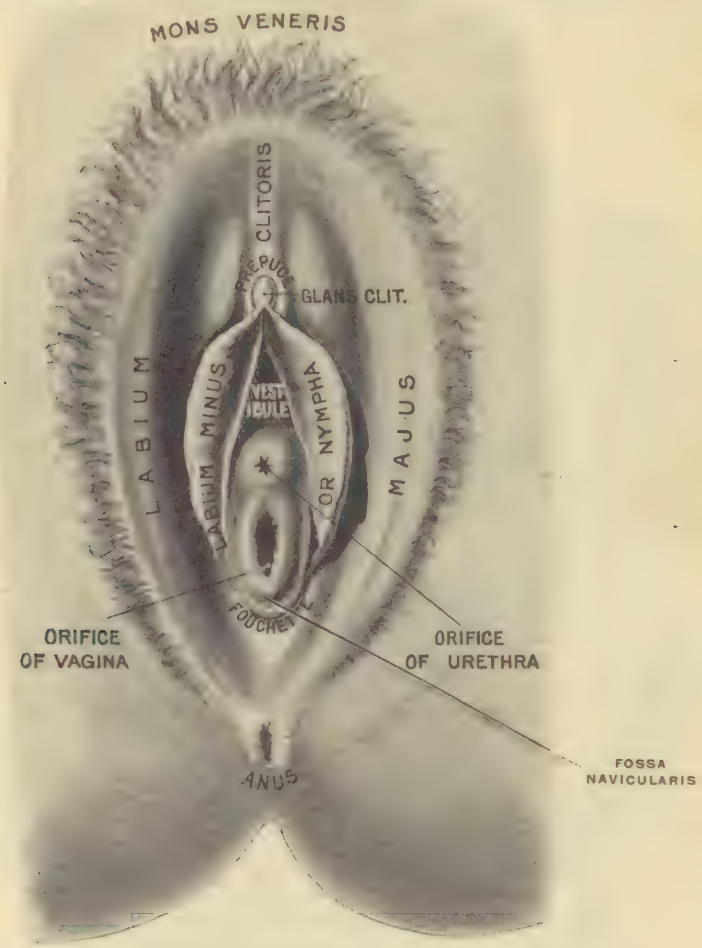

FIG. 1086.—The vulva. External female organs of generation.

glans clitoris to form the **prepuce of the clitoris** (*praeputium clitoridis*) (Fig. 1086). The internal limbs meet and unite beneath the glans clitoris and are attached to the under surface of the glans to form the **fraenum** (*frenulum clitoridis*). The nymphae are really modified skin. Their internal surfaces have numerous sebaceous follicles (*glandulae vestibulares minores*).

THE CLITORIS (Figs. 1086, 1087, 1089).

The clitoris is an erectile structure analogous to the corpora cavernosa of the penis. It is situated beneath the anterior commissure, partially hidden between the anterior extremities of the labia minora. It is connected to the rami of the os pubis. It consists of two **corpora cavernosa**, each of which (*corpus cavernosum*

clitoridis) passes behind into the **crus** (*crus clitoridis*). Each crus is attached to the ramus of the pubis and ischium; the **body** (*corpus clitoridis*) is short and concealed beneath the labia; the **free extremity** (*glans clitoridis*) is a small rounded tubercle, consisting of spongy erectile tissue, and is highly sensitive. It is provided, like the penis, with a **suspensory ligament** (*ligamentum suspensorium clitoridis*), and with two small muscles, the **Erectores clitoridis**, which are inserted into the crura of the clitoris. The two corpora cavernosa are composed of erectile

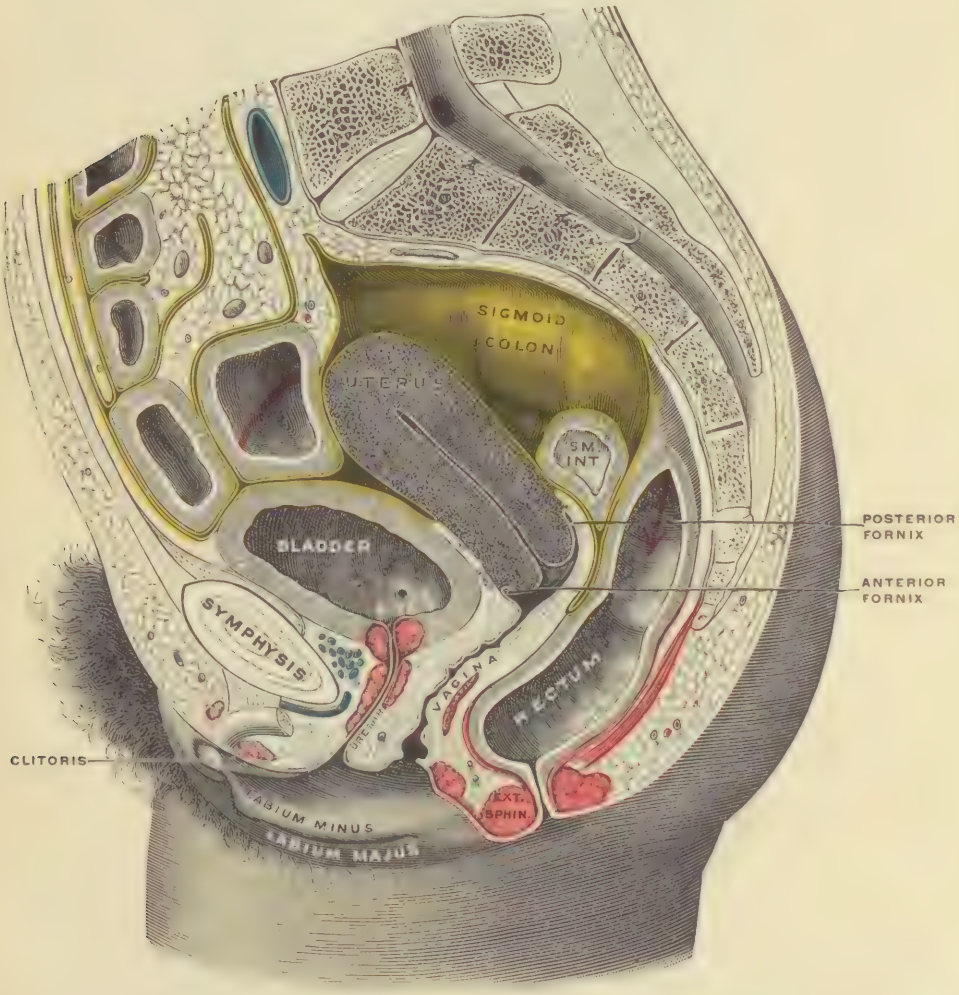

FIG. 1087.—Sagittal section of the lower part of a female trunk, right segment. SM. INT., small intestine. (Testut.)

tissue enclosed in a dense layer of fibrous membrane, united together along their inner surfaces by an incomplete fibrous pectiniform septum.

To each crus of the clitoris goes a branch from the internal pudic artery, which branch is known as the **deep artery of the clitoris**. The **dorsal arteries of the clitoris** (*arteriae dorsalis clitoridis*) from the internal pudic send branches to the glans. The **nerves** of the clitoris consist of the dorsal nerves of the clitoris from the internal pudic nerve and sympathetic fibres from the hypogastric plexus.

THE VESTIBULE (VESTIBULUM VAGINAE).

The vestibule of English and American writers is a triangular smooth surface between the clitoris and the entrance of the vagina (Fig. 1086). It is bounded on each side by the nymphae. The vestibule of the vagina is understood by the Germans to be the space at the sides of the vaginal orifice enclosed by the labii minora, as well as the space in front of the vagina.[1]

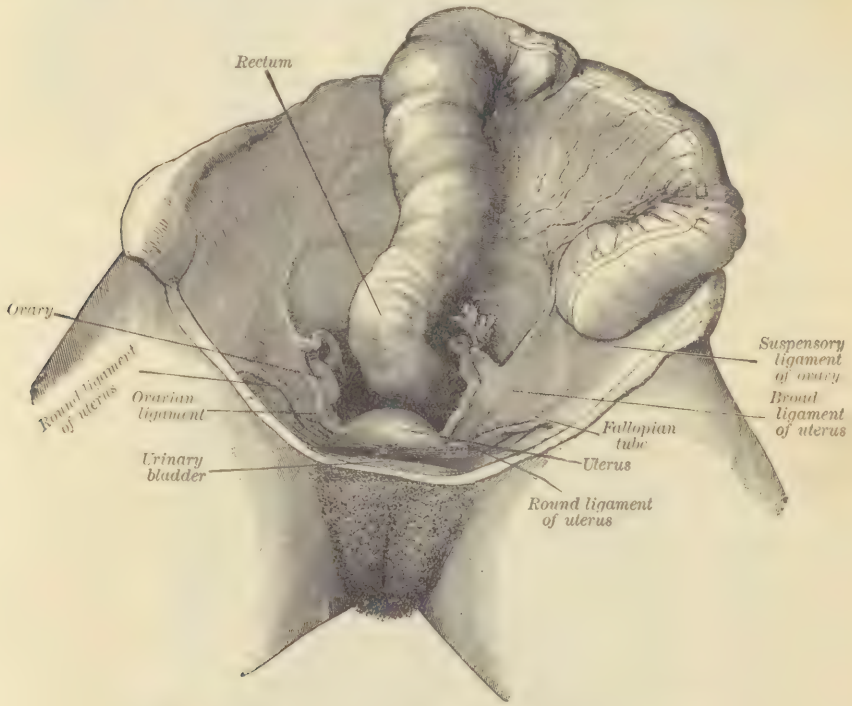

FIG. 1088.—Female pelvic organs *in situ*, seen from above. (Bardeleben.)

THE ORIFICE OF THE URETHRA OR THE MEATUS URINARIUS (ORIFICIUM URETHRAE EXTERNUM) (Figs. 1086, 1089).

The *external* orifice of the urethra or the meatus urinarius is situated at the back part of the vestibule, about an inch below the clitoris and near the margin of the vagina, surrounded by a prominent elevation of the mucous membrane. Below the meatus urinarius is the **orifice of the vagina** (*orificium vaginae*) (Fig. 1086), more or less closed in the virgin by a membranous fold, the **hymen** (Fig. 1086).

THE HYMEN (Figs. 1086, 1090).

The hymen varies much in shape. Its commonest form is that of a ring, generally broadest posteriorly; sometimes it is represented by a semilunar fold, with its concave margin turned toward the pubes. A complete septum stretched across the lower part of the vaginal orifice is called an **imperforate hymen**. Occa-

[1] See note 89 by Dr. M. Eden Paul, in vol. iv. of Toldt's Atlas.

sionally the hymen is cribriform, or its free margin forms a membranous fringe, or it may be entirely absent. It may persist after copulation, so that it cannot be considered as a test of virginity. After rupture of the hymen the small rounded elevations known as the **carunculae myrtiformes** are found as the remains of the structure.

GLANDS OF BARTHOLIN (GLANDULA VESTIBULARIS MAJOR [BARTHOLINI]) (Fig. 1089).

On each side of the posterior part of the commencement of the vagina is a round or oblong body, of a reddish-yellow color, and of the size of a horse-bean,

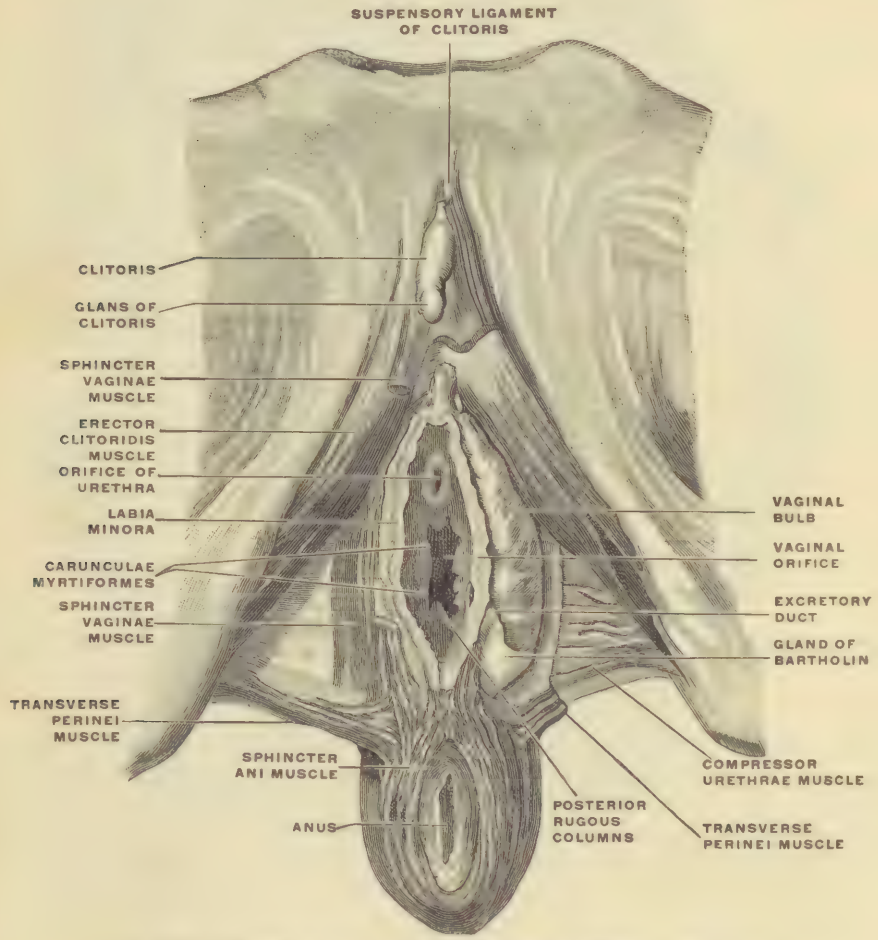

FIG. 1089.—The female external organs of generation dissected. (Spalteholz.)

analogous to Cowper's gland in the male. It is called the **gland of Bartholin**, the **gland of Duverney**, the **vulvo-vaginal gland** or the **suburethral gland** (*glandula vestibularis major* [*Bartholini*]). Bartholin's gland lies partly in the inferior or anterior leaf of the triangular ligament. The posterior portion of the bulbous vestibuli and the Bulbo-cavernous muscle partly cover it. Each gland opens by means of a long single duct immediately external to the hymen, in the angle or groove between it and the nympha (Fig. 1090).

FIG. 1090.—Varieties of hymen. (Testut, after Roze.)

THE VAGINAL BULB OR BULB OF THE VESTIBULE (BULBUS VESTIBULI) (Fig. 1089).

Extending from the clitoris, along either side of the vestibule (the term vestibule being used according to the German nomenclature) (p. 1481), and lying a little behind the nymphae, are two large oblong masses, about an inch in length, consisting of a plexus of veins enclosed in a thin layer of fibrous membrane. This plexus is superficial to the triangular ligament, and it is covered externally and inferiorly by the Bulbo-cavernous muscle. These bodies are narrow in front, rounded below, and are connected with the crura of the clitoris and rami of the pubes; they are termed by Kobelt the **bulbi vestibuli**, and he considers them analogous to the bulb of the corpus spongiosum in the male. Immediately in front of these bodies is a smaller venous plexus, continuous with the bulbi vestibuli behind and the glans clitoridis in front; it is called by Kobelt the **pars intermedia**, and is considered by him as analogous to that part of the body of the corpus spongiosum which immediately succeeds the bulb. The bulb receives its blood from the **artery of the bulb** (*arteria bulbi vestibuli*), which is a branch of the internal pudic.

INTERNAL ORGANS (PARTES GENITALES INTERNAE MULIEBRIS).

The internal organs of generation are—the **vagina**, the **uterus** and **its appendages**, the **Fallopian tubes**, the **ovaries and their ligaments**.

THE VAGINA (Figs. 1084, 1087, 1093).

The vagina extends from the vulva to the uterus. It is situated in the cavity of the pelvis, behind the bladder and in front of the rectum. Its direction is curved upward and backward, at first in the line of the pelvic outlet, and afterward in that of the axis of the cavity of the pelvis. Its walls are ordinarily in contact, and its usual shape on transverse section is that of an H, the transverse limb being slightly curved forward or backward, whilst the lateral limbs are somewhat convex toward the median line. Its length is about two and a half inches along its anterior wall (*paries anterior*), and three and a half inches along its posterior wall (*paries posterior*). It is constricted at its commencement, and becomes dilated medially, and narrowed near its uterine extremity; it surrounds the vaginal

portion of the cervix uteri, a short distance from the os, its attachment extending higher up on the posterior than on the anterior wall of the uterus (Fig. 1096).

The vaginal axis forms with the uterine axis an obtuse angle opening forward, and, as a rule, a little greater than a right angle (Fig. 1094). The fact that the attachment of the vagina to the cervix is above the external os causes the formation of a recess between the cervix and vaginal wall, known as the **vaginal fornix** (*fornix vaginae*). This recess is deeper posteriorly than it is laterally or in front. The anterior portion of the fornix is called the **anterior fornix** (Fig. 1087). The posterior portion is called the **posterior fornix** (Fig. 1087). The right and left portions are called the **right** and **left lateral fornices.** The vagina opens into the uro-genital **cleft,** between the labia minora and back of the urethra and clitoris. It opens by the **vaginal orifice** (*orificium vaginae*) (Fig. 1086). In the virgin the opening is partly closed by the hymen (p. 1481). After rupture of the hymen atrophied fragments of the torn membrane remain around the vaginal orifice, and are known as the **carunculae myrtiformes** (*caruncula hymenales*).

Relations (Figs. 1084 and 1087).—The upper part of the anterior wall of the vagina is in relation with the base of the bladder, being separated from that viscus by lax connective tissue. Lower down the middle line of the anterior wall and closely joined to it is the urethra. The upper part of the posterior wall, near the middle line, is covered for a quarter of an inch or more with peritoneum, which forms the anterior wall of the depths of the **recto-vaginal pouch of peritoneum** or **pouch of Douglas** (*excavatio rectouterina* [*Douglasi*]) (Fig. 1096), between the uterus and vagina and the rectum. The portion of the posterior wall below the level of the pouch of Douglas is placed close to the rectum, a layer of pelvic fascia intervening. As the vaginal orifice is neared, the rectum and vagina separate, and interposed between them is a mass of fibro-fatty tissue called the **perinæum** or **perineal body.** Its sides are enclosed between the Lævatores ani muscles. The ureter toward its termination (Fig. 1097) lies near the lateral wall of the vagina, passing at this point in a direction downward, inward, and slightly forward to reach the bladder. The vagina near its termination passes through the triangular ligament, and upon its sides are the bulbs of the vestibule, the glands of Bartholin, and the Bulbo-cavernous muscle.

Structure.—The vagina consists of an **internal mucous lining,** of a **muscular coat,** and between the two of a **layer of erectile tissue.**

The Mucous Membrane (*tunica mucosa*) (Fig. 1093).—The mucous membrane is continuous above with that lining the uterus. Its inner surface presents, along the anterior and posterior walls, a longitudinal ridge or raphé, called the **rugous columns of the vagina** (*columna rugarum anterior et posterior*). The anterior column extends upward as far as the external orifice of the urethra, forming the **carina urethralis vaginae.** Numerous transverse ridges or **rugae** (*rugae vaginales*) extend outward from the raphé on either side. These rugae are divided by furrows of variable depth, giving to the mucous membrane the appearance of being studded over with conical projections or papillae; they are most numerous near the orifice of the vagina, especially in females before parturition. The epithelium covering the mucous membrane is of the squamous variety. The submucous tissue is very loose and contains numerous large veins, which by their anastomoses form a plexus, together with smooth muscular fibres from the muscular coat; it is regarded by Gussenbauer as an erectile tissue (see p. 1485). It contains a number of mucous crypts, but no true glands.

The Muscular Coat (*tunica muscularis*).—The muscular coat consists of two layers: an external longitudinal, which is far the stronger, and an internal circular layer. The longitudinal fibres are continuous with the superficial muscular fibres of the uterus. The strongest fasciculi are those attached to the recto-vesical fascia on each side. The two layers are not distinctly separable from each other, but

are connected by oblique decussating fasciculi which pass from the one layer to the other. Above the triangular ligament the fibres are non-striated; in the region of the ligament they show striations. In addition to this the vagina at its lower end is surrounded by a band of striped muscular fibres, the **sphincter vaginae** (p. 461). External to the muscular coat is a layer of connective tissue containing a large plexus of blood-vessels.

The Erectile Tissue.—The erectile tissue consists of a layer of loose connective tissue situated between the mucous membrane and the muscular coat; embedded in it is a plexus of large veins, and numerous bundles of unstriped muscular fibres derived from the circular muscular layer. The arrangement of the veins is similar to that found in other erectile tissues.

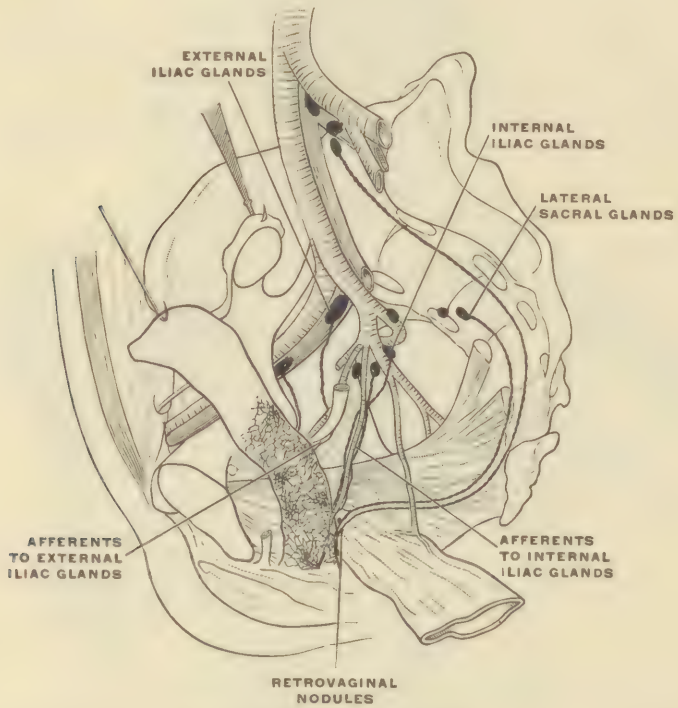

FIG. 1091.—The lymphatics of the vagina. Schematic. (Poirier and Charpy.)

Blood-vessels, Nerves, and Lymphatics.—The **arteries** of the vagina are branches of the **vesico-vaginal artery**; the **vaginal branch of the uterine artery** (p. 687), and branches of the **internal pudic** and **middle haemorrhoidal**. The **veins** form an abundant plexus around the wall of the vagina and pass to the **internal iliac veins**. The **lymphatics** (Fig. 1091) arise from the two communicating networks, one of which is below the mucous membrane, the other in the muscular wall. There is a third network around the vaginal wall, from which the collectors arise. The trunks from the upper third of the vagina pass to the **external iliac glands**; those from the middle third pass to the **internal iliac glands**; those from the lower third terminate in the **glands at the promontory of the sacrum** or in the **lateral sacral glands**.[1] The **nerves** come from the **third** and **fourth sacral nerves** and from the **utero-vaginal** and **vesical plexuses of the sympathetic.**

[1] The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.

THE WOMB OR UTERUS (Figs. 1084, 1087, 1088, 1092, 1097).

The uterus is the organ of gestation, receiving the fecundated ovum in its cavity, retaining and supporting it during the development of the fœtus, and becoming the principal agent in its expulsion at the time of parturition. It is a hollow muscular organ. The non-pregnant uterus is contained in the cavity of the pelvis between the bladder and rectum (Figs. 1087 and 1088). It is rarely placed exactly in the mid-line, but inclines to one side or the other, more often to the left than to the right. The walls of the organ are extremely thick. The uterus is movable as a whole, and the body of the uterus is movable upon the neck. Its position varies with the condition of adjacent parts, especially the bladder and rectum. The cervix is more firmly fixed than the body and fundus, and hence the latter vary more in position than the former. Normally, in an erect individual, with the bladder and rectum empty, the external os is at the level of the upper surface of the pubic symphysis (Fig. 1084) and in a frontal plane passing through the ischiatic spines. The long axis of the uterus is directed forward and upward (Fig. 1084), and is angled where the body and cervix join. Hence, normally, with the bladder

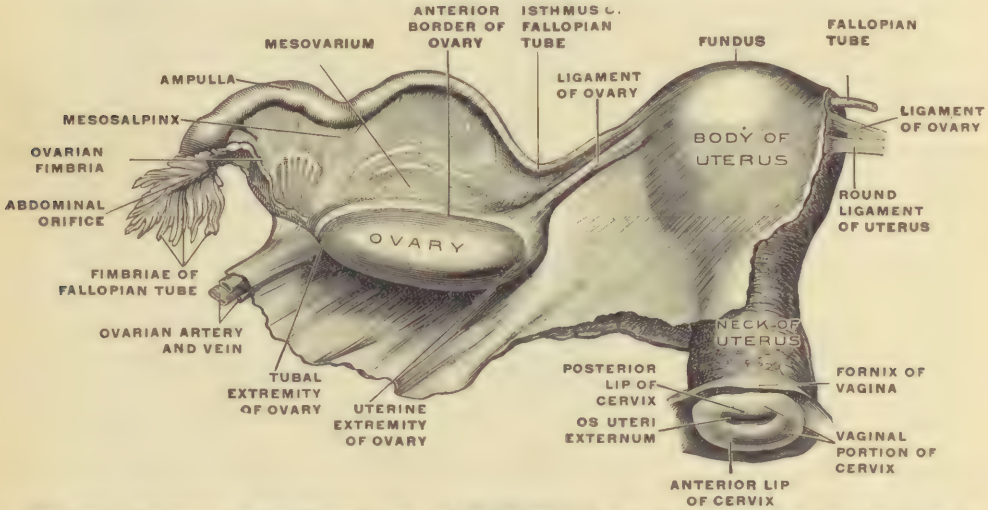

FIG. 1092. - The uterus, the left Fallopian tube and the left ovary in their connection with the broad ligament of the uterus, which has been fully unfolded. Seen from behind. From a virgin, aged nineteen years. (Toldt.)

empty, the uterus is *anteverted* and *anteflexed*. When the bladder fills the anteversion and anteflexion are almost abolished. If the bladder is overdistended and the rectum is empty, the uterus is pushed strongly backward, so that its long axis corresponds to the long axis of the vagina; in other words, it is retroverted.

In the virgin state it is pear-shaped, flattened from before backward, and is retained in its position by the round and broad ligaments on each side, and projects into the upper end of the vagina below (Figs. 1092 and 1093). Its upper end, or base, is directed upward and forward; its lower end, or apex, downward and backward, in the line of the axis of the inlet of the pelvis. It therefore forms an angle with the vagina, since the direction of the vagina corresponds to the axis of the cavity and outlet of the pelvis. The non-pregnant adult uterus measures about three inches in length, two inches in breadth at its upper part, and nearly an inch in thickness, and it weighs from an ounce to an ounce and a half.

It consists of two parts (Fig. 1092): (1) An upper and larger portion, consisting of the body and fundus. This portion is flattened from before backward. (2) A lower, smaller, and cylindrical portion, the cervix.

The Fundus (*fundus uteri*) (Fig. 1092).—The fundus is the upper broad extremity of the uterus. If a line is drawn from the uterine opening of one Fallopian tube to the other, the portion above the line is the fundus. The fundus is directly continuous with the body.

The Body of the Uterus (*corpus uteri*) (Fig. 1092).—The body of the uterus is below and continuous with the fundus. In outline, when seen from in front or behind, it resembles a triangle, the base being above and the point being absent.

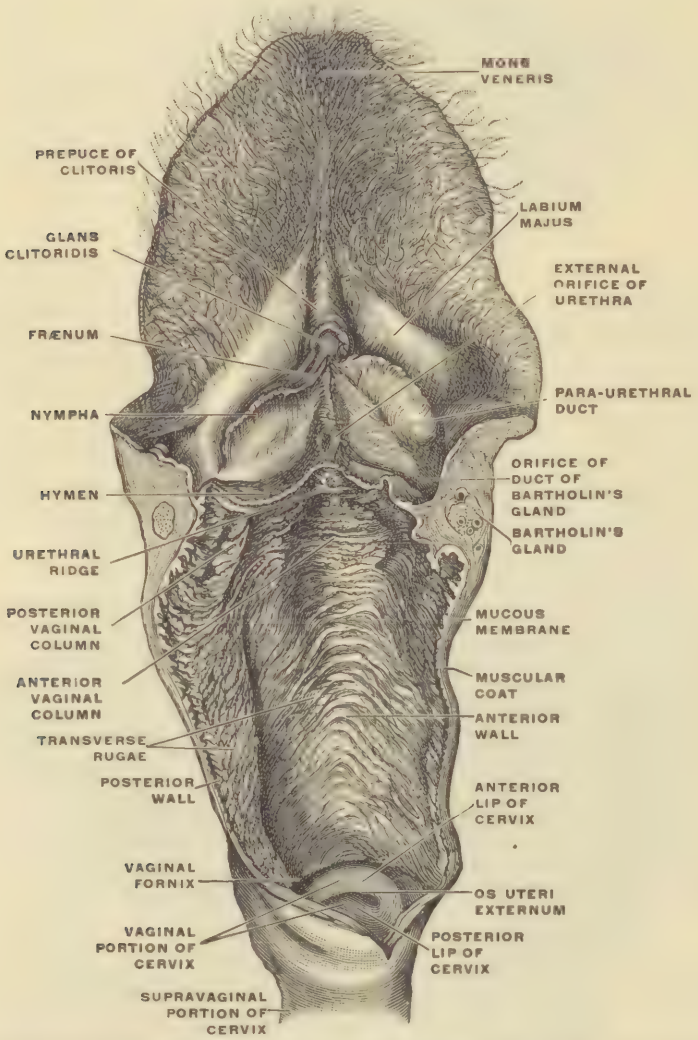

FIG. 1093.—The female external genital organs of a virgin attached to the vagina, which has been isolated and opened, and a portion of the cervix uteri. (Toldt.)

The **anterior surface** (*facies vesicalis*) passes on each side into the **posterior surface** (*facies intestinalis*) by the **lateral border** (*margo lateralis*).

The body gradually narrows from the fundus to the neck. Its anterior surface is so slightly rounded as to appear flattened. It is covered by peritoneum (Fig. 1092), which becomes separated from it at its union with the cervix, in order to form the **utero-vesical pouch**, which lies between the uterus and bladder (Fig. 1096). Its posterior surface is more rounded than the anterior, being convex transversely. It is

covered by peritoneum throughout (Fig. 1097), and separated from the rectum by some convolutions of the small intestine (Fig. 1087). The peritoneum which covers the posterior surface forms most of the anterior wall of Douglas's *cul-de-sac* (Figs. 853, 1096 and 1097, and p. 1248). Its lateral margins (Figs. 1092 and 1097) are concave, and each gives attachment to the Fallopian tube above, the round ligament below, and in front of this the ligament of the ovary; behind both of these structures, and from the side of the womb the broad ligament passes. The division between the

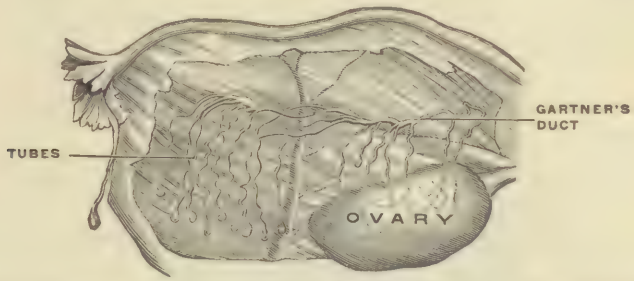

FIG. 1094.—The parovarium. The mesosalpinx is partly removed. (Poirier and Charpy.)

the body and the cervix is indicated externally by a slight constriction, and by the reflection of the peritoneum from the anterior surface of the uterus on to the bladder, and internally by a narrowing of the canal called the **internal os** (Fig. 1095).

The Neck or Cervix Uteri (Figs. 1092 and 1095).—The neck or cervix uteri is the lower constricted segment of the uterus; around its circumference is attached the upper end of the vagina (Figs. 1087, 1092, 1093, and 1096), which extends upward a greater distance behind than in front. The neck is spindle-shaped in those who have had no children, cylindrical in those who have had children.

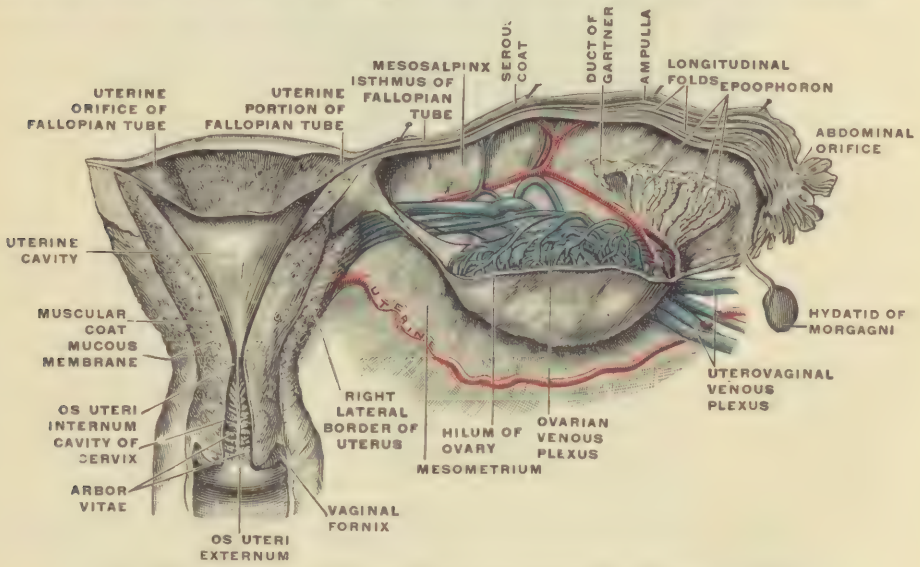

FIG. 1095.—The uterus and the right Fallopian tube opened from behind. (Toldt.)

The Supravaginal Portion (*portio supravaginalis [cervicis]*) (Figs. 1092 and 1096).—The supravaginal portion is not covered by peritoneum in front; a pad of cellular tissue is interposed between it and the bladder. Behind, the peritoneum is extended over it.

The Vaginal Portion (*portio vaginalis cervicis*) (Figs. 1087, 1092, 1093, and 1096).—The vaginal portion is the lower end projecting into the vagina. It is round or

elliptical, the long axis of the elliptical figure being transversely placed. On its surface is a small aperture, the **external mouth of the womb**, or **os uteri**, or **external os** (*orificium uteri externum*) (Figs. 1092, 1093, 1095, and 1096), generally circular in shape, but sometimes oval or almost linear. If a woman has borne children the opening is transverse and the margins are irregular. The margin of the opening is, in the absence of past parturition or disease, quite smooth. This aperture divides the vaginal portion of the cervix into two lips, an **upper** or **posterior lip** (*labium posterius*) and a **lower** or **anterior lip** (*labium anterius*). On each side of the cervix and upper portion of the vagina there is a space containing bloodvessels and filled with loose cellular tissue. This loose tissue passes upward between the layers of the broad ligament and is called **parametrium.** On each side of the cervix and three-quarters of an inch away is the terminal portion of the corresponding ureter.

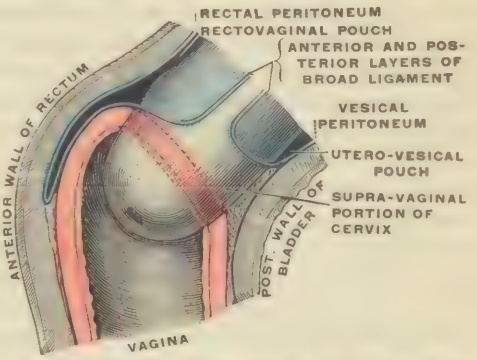

FIG. 1096. The cervix uteri and upper end of the vagina, showing their relations to the peritoneum. Diagrammatic. (Testut.)

Folds and Ligaments.—The ligaments of the uterus are eight in number. Some are simple folds of peritoneum; others contain connective tissue and muscle. The ligaments are as follows: one

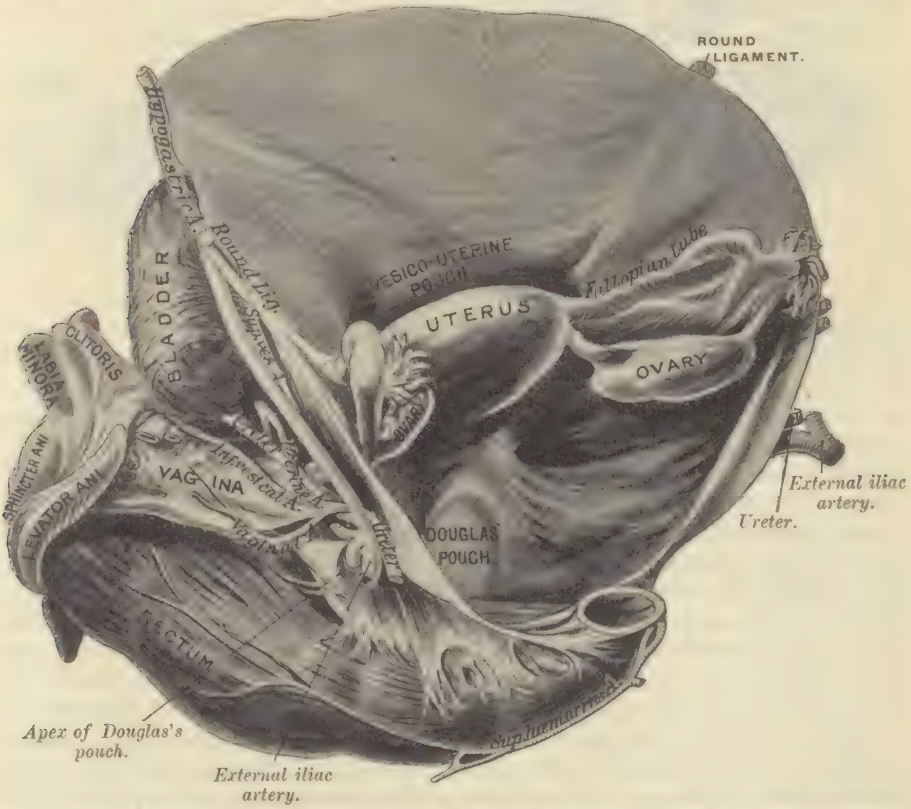

FIG. 1097.—Douglas's pouch. (From a preparation in the Museum of the Royal College of Surgeons of England.)

anterior, one **posterior**, two **lateral** or **broad**, two **sacro-uterine**—all these being formed of peritoneum—and, lastly, two **round ligaments.**

The **Anterior Ligament** or the **Utero-vesical Fold** or **Vesico-uterine Ligament** is reflected on to the bladder from the front of the uterus, at the junction of the cervix and body. It forms the **utero-vesical pouch** (*excavatio vesicouterina*) (Figs. 1096 and 1097).

The **Posterior Ligament** or the **Recto-vaginal Fold** passes from the posterior wall of the uterus over the upper fourth of the vagina, and thence on to the rectum and sacrum. It thus forms a pouch, called the **recto-vaginal pouch** or **Douglas's pouch** (Figs. 853, 1096, and 1097), the boundaries of which are, in front, the posterior wall of the uterus, the supravaginal portion of the cervix, and the upper fourth of the vagina; behind, the rectum and sacrum; above, the small intestine; and, laterally, the folds of Douglas or recto-uterine folds, which contain the sacro-uterine ligaments.

The **Lateral** or **Broad Ligament** (*ligamentum latum uteri*) (Figs. 1088, 1098, and 1104) is a peritoneal fold which passes from each side of the uterus to the lateral wall of the pelvis as high as the external iliac vein. From this region comes the peritoneal fold called the suspensory ligament of the ovary (Fig. 1088). The two broad ligaments form a septum across the pelvis, which divides that cavity into two portions. In the anterior part are contained the bladder, urethra, and vagina; in the posterior part, the rectum. In the uterus normally placed the anterior surface of the broad ligament faces forward and downward, and the posterior surface faces upward and backward. The ligament is more nearly vertical

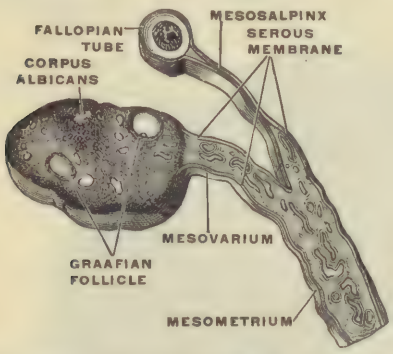

FIG. 1098.—The broad ligament of the uterus, with the mesovarium, the mesosalpinx, the ovary, and the Fallopian tube in transverse section. (Toldt.)

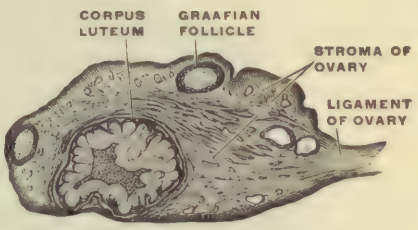

FIG. 1099.—Longitudinal section through the ovary. (Toldt.)

at its pelvic insertion. The two layers of the broad ligament are mostly near to each other, to the side and below they separate and pass into the peritoneum of the lateral pelvic wall, the bladder and the rectum. Between the two layers of each broad ligament are contained—(1) the Fallopian tube superiorly; (2) the round ligament; (3) the ovary and its ligament; (4) the parovarium or organ of Rosenmüller, and the paro-ophoron; (5) loose connective tissue, which is called **parametrium**; (6) unstriped muscular fibre; and (7) blood-vessels and nerves. The Fallopian tube is in the free edge of the broad ligament, and is contained in a special fold, which is attached to the part of the ligament near the ovary, and is known by the name of the **mesosalpinx** (Figs. 1094, 1098, and 1104). If the mesosalpinx is spread out, it is seen to be roughly triangular; the base of the triangle is outward, the apex at the upper and outer angle of the uterus; the upper boundary is the Fallopian tube, and the lower boundary is the ovary and its ligament. Between the two layers of the mesosalpinx are the parovarium and the paro-ophoron. Between the fimbriated extremity of the tube and the lower attachment of the broad ligament is a concave rounded margin, called the **infundibulo-pelvic ligament** (Fig. 1103).

The ovary lies in a depression of the broad ligament called the **ovarian bursa** (*bursa ovarii*) (Figs. 1098 and 1104), and is joined to the ligament by a short fold, the **mesovarium** (Fig. 1104).

The **mesovarium** passes upward from the posterior surface of the broad ligament (Fig. 1098). Beneath the mesovarium is a larger and thicker portion of the broad ligament, called the **mesometrium** (Fig. 1098).

The **Sacro-uterine** or **Utero-sacral Ligaments** (*plicae rectouterinae*) are contained in the peritoneal folds of Douglas. They pass from the second and third bones of the sacrum, downward and forward on the lateral aspects of the rectum to be attached one on each side of the uterus at the junction of the supravaginal cervix and the body, this point corresponding internally to the position of the os internum. They contain fibrous tissue and unstriated muscle-fibre. Muscular fibres from the uterine wall to the rectal wall constitute the **Recto-uterinus muscle** (*musculus rectouterinus*). This muscle is part of the sacro-uterine ligaments.

A **Round Ligament** (*ligamentum teres*) (Figs. 1088, 1097, 1100, and 1104) is attached on each side of the uterus. The two ligaments are rounded cords, between four and five inches in length, each situated between the layers of the broad ligament in front of and below the Fallopian tube. Commencing at the superior angle of the uterus, this ligament passes forward, upward, and outward through the internal abdominal ring, along the inguinal canal, to the labium majus, in which it becomes lost. The round ligament consists principally of muscular tissue prolonged from the uterus; also of some fibrous and areolar tissue, besides blood-vessels and nerves, enclosed in a duplicature of peritoneum, which in the fœtus is prolonged in the form of a tubular process for a short distance into the inguinal canal. This process is called the **canal of Nuck**. It is generally obliterated in the adult, but sometimes remains pervious even in advanced life. It is analogous to the peritoneal pouch which precedes the descent of the testis.

The Cavity of the Uterus (*cavum uteri*) (Fig. 1095).—The cavity of the uterus is small in comparison with the size of the organ, because of the great thickness of the wall. That portion of the cavity which corresponds to the body is triangular, flattened from before backward, so that its anterior and posterior walls are closely approximated, and having its base directed upward toward the fundus. At each superior angle is a funnel-shaped cavity, which constitutes the remains of one division of the body of the uterus into two cornua, and at the bottom of each cavity is the minute orifice of the Fallopian tube. At the inferior angle of the uterine cavity is a small constricted opening, smaller and more nearly circular than the external os uteri, the **internal orifice of the uterus** or **internal os uteri** (*orificium internum uteri*) (Fig. 1095), which leads into the cavity of the cervix.

The Cavity of the Cervix or Cervical Canal (*canalis cervicis uteri*) (Fig. 1095).—The cavity of the cervix or cervical canal extends from the internal os uteri to the external os uteri. It is somewhat fusiform, flattened from before backward, broader at the middle than at either extremity, and communicates below with the vagina. The wall of the canal presents, anteriorly and posteriorly, a longitudinal column, from which proceed a number of small oblique columns, giving the appearance of branches from the stem of a tree; and hence the name **uterine arbor vitae** (*plicae palmatae*) applied to it. These folds usually become very indistinct after the first labor.

Structure.—The uterus is composed of three coats: an **external** or **serous coat**, a **middle** or **muscular coat**, and an **internal mucous** or **coat.**

The Serous Coat or Perimetrium (*tunica serosa*) (Figs. 1087, 1092, 1096, and 1097).—The serous coat is derived from the peritoneum; it invests the fundus and the whole of the posterior surface of the uterus; but covers the anterior surface only as far as the junction of the body and cervix. In the lower fourth of the posterior surface the peritoneum, though covering the uterus, is not closely connected with

it, being separated from it by a layer of loose cellular tissue and some large veins. At the lateral margins of the uterus the serous coat passes on to the broad ligaments. The serous coat adheres closely to the uterus, and it is very difficult to separate it from the muscle.

The Muscular Coat (*tunica muscularis*) (Fig. 1095).—The muscular coat forms the chief bulk of the substance of the uterus. In the unimpregnated state it is dense, firm, of a grayish color, and cuts almost like cartilage. It is thick opposite the middle of the body and fundus, and thin at the orifices of the Fallopian tubes. It consists of bundles of unstriped muscular fibres, disposed in layers, intermixed with areolar tissue, blood-vessels, lymphatic vessels, and nerves. The muscular tissue is disposed in three layers—**external, middle,** and **internal.**

The **external layer** is placed beneath the peritoneum, disposed as a thin plane on the anterior and posterior surfaces. It consists of fibres which pass transversely across the fundus, and, converging at each superior angle of the uterus, are continued on the Fallopian tube, the round ligament, the ligament of the ovary; some passing at each side into the broad ligament, and others running backward from the cervix into the sacro-uterine ligaments. The fibres of the external portion of the outer layer (*stratum subserosum*) are longitudinal. The fibres of the inner portion of the outer layer (*stratum supravasculare*) are partly circular and partly longitudinal.

The **middle layer of fibres** (*stratum vasculare*), which is thickest, presents bundles of circular fibres closely connected with blood-vessels. In this layer are most of the blood-vessels. The circular fibres about the internal os form a distinct sphincter. Those which surround the orifices of the Fallopian tubes are arranged in the form of two hollow cones, the apices of which surround the orifices of the Fallopian tubes, their bases intermingling with one another on the middle of the body of the uterus.

The **internal** or **deep layer** (*stratum mucosum*) consists of longitudinal fibres. Some consider the deeper portion of the muscular tissue of the uterus to be the muscularis mucosae. But the deep portion of the muscular substance is continuous with the more superficial portion, and there is no submucous coat between the muscle and the mucous membrane. The deeper layer of muscular fibres of the uterus contains connective tissue and elastic fibres. The muscular tissue of the cervix contains more connective and elastic tissue than does the body of the uterus; hence, the cervix is harder and stiffer than the body.

The Mucous Membrane (*tunica mucosa*) (Fig. 1095).—The mucous membrane is thin, smooth, and closely adherent to the subjacent muscular tissue. It is continuous, through the fimbriated extremity of the Fallopian tubes, with the peritoneum, and through the os uteri with the lining of the vagina.

In the body of the uterus it is smooth, soft, of a pale-red color lined with columnar ciliated epithelium, and presents, when viewed with a lens, the orifices of numerous tubular follicles arranged perpendicularly to the surface. It is unprovided with any submucosa, but is intimately connected with the innermost layer of the muscular coat. In structure its **corium** differs from ordinary mucous membrane, consisting of an embryonic nucleated and highly cellular form of connective tissue, in which run numerous large lymphatics. In it are the tube-like **uterine glands** (*glandulae uterinae*), which are of small size in the unimpregnated uterus, but shortly after impregnation become enlarged and elongated, presenting a contorted or waved appearance toward their closed extremities, which reach into the muscularis, and may be single or bifid. The uterine glands consist of a delicate membrane, lined with epithelium, which becomes ciliated toward the orifices.

In the **cervix** the mucous membrane is sharply differentiated from that of the uterine cavity. It is thrown into numerous oblique ridges, which diverge from an anterior and posterior longitudinal raphé, presenting an appearance which has

received the name of **arbor vitae**. In the upper two-thirds of the canal the mucous membrane is provided with numerous deep glandular follicles (*glandulae cervicales uteri*), which secrete a clear viscid alkaline mucus; and in addition, extending through the whole length of the canal, are a variable number of little cysts, presumably follicles, which have become occluded and distended with retained secretion. They are called the **ovules of Naboth**. The mucous membrane covering the lower half of the cervical canal presents numerous papillae. The epithelium of the upper two-thirds is cylindrical and ciliated, but below this it loses its cilia, and gradually changes to squamous epithelium close to the external os.

The Uterus at Different Ages.—The uterus of the fœtus is in the abdominal cavity projecting above the brim of the pelvis. The cervix is considerably larger than the body. At birth the cervix is larger relatively than in the adult; there is no distinct internal os distinguishing the cavity of the body of the uterus from the cavity of the cervix, and "the arbor vitae extends throughout the whole length of the uterus."[1] The growth of the uterus is slow until puberty is almost reached, when for a time the growth is rapid. The growth of the uterine body causes the mucous membrane of this part to lose its folds, hence the arbor vitae disappears from the body. In a woman who has had children the uterine cavity is larger than in a woman who has never borne a child. In advanced years the uterine wall becomes paler and hard and rigid from atrophic fibrous changes. A more distinct constriction separates the body and cervix. The internal os frequently and the external os occasionally are obliterated in old age.

Abnormalities.—Very rarely the uterine cavity is divided into two by a septum. Occasionally the condition known as **bicornate uterus** exists. In this condition each lateral angle is prolonged into a horn or cornu. The uterus is formed by the union of the two ducts of Müller, and failure of fusion of these ducts makes a double uterus or a bicornate uterus.

Changes at a Menstrual Period.—For several days before the menstrual flow begins the mucous membrane increases in thickness and vascularity and its surface is cast into folds. After these preparatory changes the superficial portions of the mucous membrane break down and are cast off, and bleeding begins. At the termination of menstruation the mucous membrane rapidly regenerates. At each menstrual period from 100 to 200 grammes of blood are discharged. The meaning of menstruation is uncertain. Pflüger believes the wall of the uterus is made raw, so that if an impregnated ovum arrives it will adhere. Reichert believes that menstruation means that no impregnated ovum has arrived in the womb, and hence no bed is needed for one.

Changes Induced by Pregnancy.—The muscular fibres hypertrophy enormously and become vastly longer and broader. There is a great increase in connective tissue, and new connective-tissue fibres pass between bundles of muscle. The peritoneal coat undergoes hyperplasia. It remains closely adherent to the uterus, except over the lower segment, from which region it can be easily stripped. The blood-vessels become large and tortuous. The nerves are increased in length and new filaments form. The lymphatics undergo hypertrophy and hyperplasia (Prof. Barton Cooke Hirst). The uterus becomes spherical, and after the fourth month ovoidal. Early in pregnancy the increase in weight causes the uterus to descend in the pelvis. After the third month it rises progressively, and during the ninth month the fundus reaches the epigastrium. "Before term (four weeks in primiparae, ten days or one week in multiparae) the fundus sinks again, as the presenting part and lower uterine segment become engaged in the pelvic cavity. This phenomenon is explained by contraction of the overstretched abdominal walls."[2] The womb is acutely anteflexed during the first three months

[1] Prof. Francis A. Dixon in Prof. Cunningham's Text-book of Anatomy.
[2] A Text-book of Obstetrics. By Prof. Barton Cooke Hirst.

of pregnancy. After this period, as the womb rises, the anteflexion is diminished, but some degree remains, because the abdominal walls are too lax to hold the organ straight. The uterus passes somewhat to the right side and undergoes a rotation on its longitudinal axis, so that the anterior surface looks front and to the

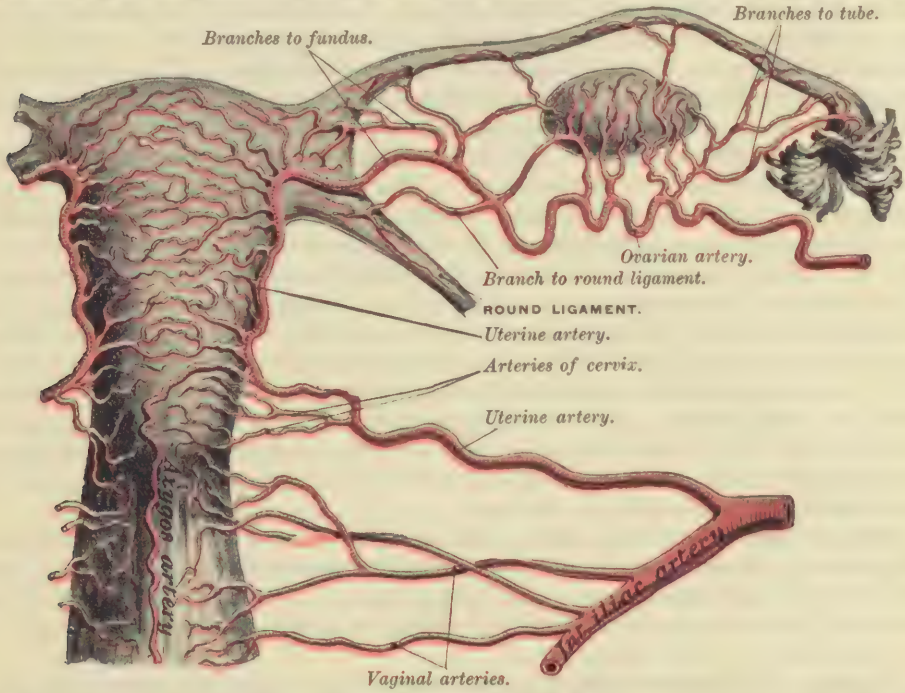

FIG. 1100.—The arteries of the internal organs of generation of the female, seen from behind. (After Hyrtl.)

right. These changes in position are caused by fecal distention of the sigmoid. The intestines are above and back of the uterus. During the first four months the cervix softens and enlarges somewhat. The length of the cervical canal is not

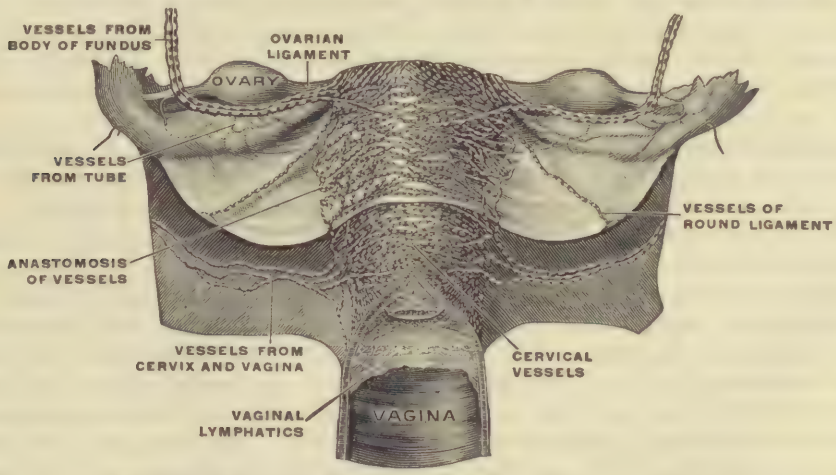

FIG. 1101.—The lymphatic vessels of the uterus. (Poirier and Charpy.)

altered during pregnancy, and the canal does not dilate until labor begins. During pregnancy the cervical glands secrete thick mucus, which coagulates and occludes the cervical canal; the round ligaments become stronger, and the layers of the broad ligament are separated toward their inner portions by the enlarging womb.

After parturition the uterus nearly regains its former size, usually weighing something over one and a half ounces; but its cavity is larger than in the virgin state, the external orifice is more marked, its edges present a fissured surface, its vessels are very tortuous, and its muscular layers are more defined.

Vessels and Nerves (Fig. 1100).—The **arteries of the uterus** are the **uterine,** from the internal iliac, and the **ovarian,** from the aorta. They are remarkable for their tortuous course in the substance of the organ and for their frequent anastomoses. The uterine artery reaches the lower part of the uterus at the side and is pro-

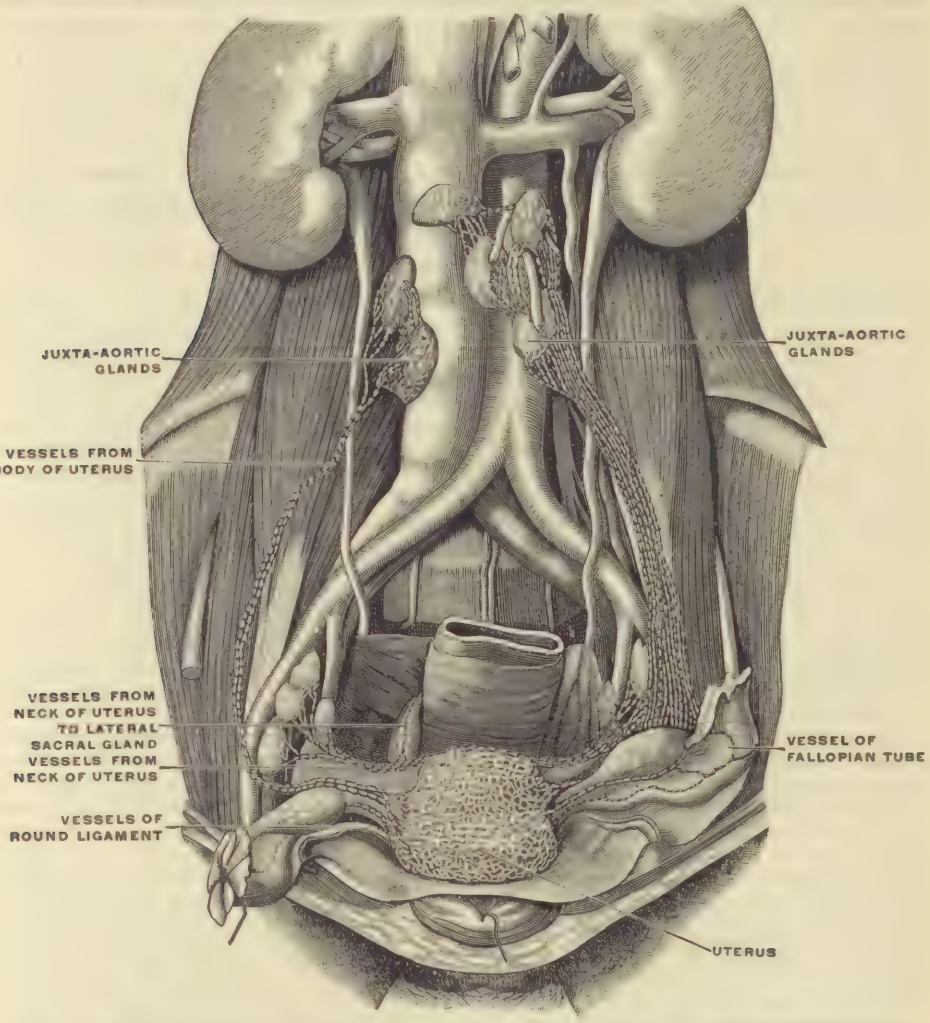

FIG. 1102.—The lymphatics of the internal organs of generation in the female. (Poirier and Charpy.)

longed as a large artery to the body and fundus, which ascends between the layers of the broad ligament. The uterine artery gives off a smaller branch, the **cervical,** which descends to supply the cervix and sends **cervico-vaginal** branches to the vagina. The **azygos arteries of the vagina** come from the cervico-vaginal reinforced by branches of the vaginal arteries (Fig. 1104). A median longitudinal vessel is formed in front and behind, which descends in the vaginal wall. The termination of the ovarian artery meets the termination of the uterine artery, and forms an anastomotic trunk from which branches are given off to supply the uterus. Dr. Byron Robinson, instead of describing the uterine and ovarian

arteries as two vessels, describes them as parts of one vessel, the **arteria uterina ovarica** (p. 558). The **veins** are of large size, and correspond with the arteries. In the impregnated uterus these vessels form the **uterine sinuses**, consisting of the lining membrane of the veins adhering to the walls of the canals channelled through the substance of the uterus. They terminate in the **uterine plexuses**, which empty into the **internal iliac veins**. The **lymphatics** (Figs. 1101 and 1102) originate from three networks, a muscular network, a peritoneal network, and a network in the stroma. The trunks from these networks anastomose, and thus form another network beneath the peritoneum, and from the fourth network the collectors arise. The network of the cervix is continuous with that of the body. The collecting trunks from the cervical region number from five to eight. Some terminate in the **external iliac glands**, some in the **internal iliac glands**, some in the **lateral sacral glands**, or the **glands of the promontory**. The collecting trunks from the body terminate chiefly in the **juxta-aortic** or **pre-aortic glands**, but some terminate in the **external iliac glands**, and some in the **inguinal glands**.[1] The **nerves** come chiefly from the **utero-vaginal plexus**, which continues into the **hypogastric plexus** and receives filaments from the **third** and **fourth sacral nerves**. The uterus also receives direct fibres from the **hypogastric plexus** and from the **vesical plexus**.

Surgical Anatomy.—*Pelvic cellulitis* (*parametritis*) is inflammation of the pelvic cellular tissue. It is due to sepsis, and its usual antecedent is uterine sepsis. A laceration of the cervix may admit bacteria. An abscess may form. If it points in the vagina it should be incised through the vaginal wall. The uterus may require removal (*hysterectomy*) in cases of *malignant disease* or for *fibroid tumors*. *Carcinoma* is the most common form of malignant disease of the uterus, though cases of *sarcoma* do occur. Carcinoma may show itself either as a columnar carcinoma or as a squamous carcinoma; the former commencing either in the cervix or body of the uterus, the latter always commencing in the epithelial cells of the mucous membrane covering of the vaginal surface of the cervix. The columnar form may be treated in the early stage, before fixation has taken place, by removal of the uterus, either through the vagina or by means of abdominal section. The former operation is attended by the smaller death-rate. Vaginal hysterectomy may be performed in any case in which the uterus or the uterus and tumor are not too large to be withdrawn through the vagina. It is difficult in this operation to deal with adhesions and other complications in the upper part of the pelvis, and for this reason many surgeons prefer the abdominal operation. *Vaginal hysterectomy* is performed by placing the patient in the lithotomy position and introducing a large duckbill speculum into the vagina. The cervix is then seized with a volsellum and pulled down as far as possible and the mucous membrane of the vagina incised around the cervix as near to it as the disease will allow, especially in front, where the ureters are in danger of being wounded. A pair of dressing forceps are then pushed through into Douglas's pouch and opened sufficiently to allow of the introduction of the two forefingers, by means of which the opening is dilated laterally as far as the sacro-uterine ligaments. A somewhat similar proceeding is adopted in front, but here the bladder has to be separated from the anterior wall of the uterus for about an inch before the vesico-uterine fold of peritoneum can be reached. This is done by carefully burrowing upward with a director and stripping the tissues off the anterior uterine wall. When the vesico-uterine pouch has been opened and the opening dilated laterally, the uterus remains attached only by the broad ligaments, in which are contained the vessels that supply the uterus. Before division of the ligaments, these vessels have to be dealt with. The forefinger of the left hand is introduced into Douglas's pouch and an aneurism needle, armed with a long silk ligature, is inserted into the vesico-uterine pouch, and is pushed through the broad ligament of one side about an inch above its lower level and at some distance from the uterus. One end of the ligature is now pulled through the anterior opening, and in this way we have the lowest inch of the broad ligament, in which is contained the uterine artery, enclosed in a ligature. This is tied tightly, and the operation is repeated on the other side. The broad ligament is then divided on either side, between the ligature and the uterus, to the extent to which it has been constricted. By traction on the volsellum which grasps the cervix, the uterus can be pulled considerably farther down in the vagina, and a second inch of the broad ligament is treated in a similar way. This second ligature will embrace the pampiniform plexus of veins and, when the broad ligament has been divided on either side, it will be found that a third ligature can be made to pass over the Fallopian tube and top of the broad ligament, after the uterus has been dragged down as far as possible. After the third ligature has been tied and the structures between it and the uterus divided, this organ will be freed from all its connections and can be removed from the vagina. This canal is then sponged out and lightly dressed with gauze,

[1] The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.

no sutures being used. The gauze may be removed at the end of the second day. In squamous epithelioma, amputation of the cervix is done by some in those cases where the disease is recognized before it has invaded the walls of the vagina or the neighboring broad ligaments. The operation consists in removing a wedge-shaped piece of the uterus, including the cervix, through the vagina and attaching the cut surfaces of the stump to the anterior and posterior vaginal walls, so as to prevent retraction. In view, however, of the continuity of the lymphatic network of the cervix with the lymphatics of the body, the operation is insufficient and should be condemned. Complete *abdominal hysterectomy* is rarely necessary, except for malignant disease. In this operation the entire uterus is removed. The preliminary introduction of bougies into the ureters as practised by Kelly and Clark enables the surgeon to readily recognize the situations of these tubes. After the abdomen has been opened the uterine vessels are secured and the broad ligaments divided in a similar manner to that employed in vaginal hysterectomy, except that the proceeding is commenced from above. When the first two ligatures have been tied and the broad ligament divided, it will be found that the uterus can be raised out of the pelvis. A transverse incision is now made through the peritoneum, where it is reflected from the anterior surface of the uterus on to the back of the bladder and the serous membrane peeled from the surface of the uterus until the vagina is reached. The anterior wall of this canal is cut across. The uterus is now turned forward and the peritoneum at the bottom of Douglas's pouch incised transversely, and the posterior wall of the vagina cut across until it meets the incision on the anterior wall. The uterus is now almost free, and is held only by the lower part of the broad ligament on either side, containing the uterine artery. A third ligature is made to encircle this, and, after having been tied, the structures are divided between the ligature and the uterus. The organ can now be removed. The vagina is plugged with gauze, and the external wound closed in the usual way. The vagina acts as a drain, and therefore the opening into it is usually left unsutured. In some cases of uterine fibroid the abdomen is opened and the tumor is removed, but the uterus is not taken away. This operation is called *myomectomy*. This operation is suited only to solitary subperitoneal or interstitial tumors (Penrose).

The common operation for uterine fibroids is *supravaginal amputation*. The uterus is cut away and the cervical flaps are sutured. Before the technique of hysterectomy was perfected and before myomectomy was devised the favorite operation for uterine fibroids was *salpingo-oöphorectomy*, and by it a large majority of cases operated upon were cured. When it succeeds a premature menopause is induced and the tumor shrinks. The operation is useless if a woman is past the menopause, and is apt to fail if the tumor is very soft or very large.

THE ADNEXA OR APPENDAGES OF THE UTERUS.

The appendages of the uterus are the **Fallopian tubes**, the **ovaries** and **ovarian ligaments**, and the **round ligaments**. They are placed in the following order: in front is the round ligament; the Fallopian tube occupies the upper margin of the broad ligament; the ovary and its ligament are behind and below both.

THE FALLOPIAN TUBE (TUBA UTERINA [FALLOPII]) (Figs. 1092, 1097, 1098, 1103, 1104).

The Fallopian tubes or oviducts convey the ova from the ovaries to the cavity of the uterus. They are two in number, one on each side, situated in the upper margin of the broad ligament, extending from each superior angle of the uterus to the sides of the pelvis. Each tube is about four inches and a quarter in length, and is placed in a fold of peritoneum, which is part of the broad ligament and is called the **mesosalpinx** (Fig. 1098). Each tube is described as consisting of four portions: (1) the **isthmus** (*isthmus tubae uterinae*) (Fig. 1103), or inner constricted third; (2) the **ampulla** (*ampulla tubae uterinae*) (Fig. 1103), or outer dilated portion, which curves over the ovary; and (3) the **infundibulum**, the funnel-like expansion of the tube, at the bottom of which is the **abdominal orifice** or **pavilion** (*ostium abdominale tubae uterinae*) (Fig. 1103). The abdominal orifice has a small diameter (2 mm. when relaxed to its full extent). The margin of the infundibulum is rendered irregular by the presence of numerous small processes, the **fimbriae** (*fimbriae tubae*). This end of the tube is called the **fimbriated extremity** (Fig. 1103), because of these processes. The surfaces of the fimbriae looking into the cavity of the infundibulum are covered with mucous membrane continuous with the tubal mucous

membrane. The outer surfaces are covered with peritoneum. One of the fimbriae is attached to the ovary and is called the ovarian fimbria (*fimbria ovarica*) (Fig. 1103). (4) The **uterine portion** of the tube (*pars uterina*) (Fig. 1095) is in the uterine wall. The opening into the uterus (*ostium uterinum tubae*) is even smaller than the abdominal opening, and will admit only a small bristle. The general direction of the Fallopian tube is outward, backward, and downward. In connection with the fimbriae of the Fallopian tube or with the broad ligament close to them there is frequently one or more small vesicles floating on a long stalk of peritoneum. These are termed the **hydatids of Morgagni** (*appendices vesiculosi*). They are representative of small portions of the upper extremity of the Wolffian duct.

Course Pursued by the Fallopian Tube (Figs. 1088 and 1103).—The tube on each side begins at the upper and outer angle of the uterus and passes outward in a horizontal direction toward the uterine extremity of the ovary. It then bends almost to a right angle and ascends close to the pelvic wall and in front of the anterior margin to the tubal extremity of the ovary. At this point it turns sharply

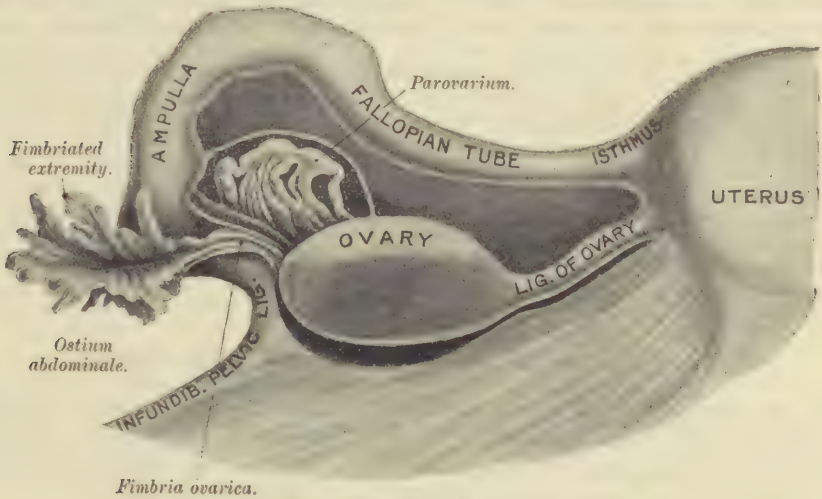

FIG. 1103.—Uterine appendages, seen from behind. (Henle.)

downward and a little backward, and the inner surface of the infundibulum comes to lie upon the free margin and the posterior portion of the inner surface of the ovary. "The fimbria ovarica thus ascends in a recurrent direction to the extremitas tubaria."[1]

Structure.—The Fallopian tube consists of three coats—**serous, muscular**, and **mucous.**

The **external** or **serous coat** (*tunica serosa*) (Fig. 1098) is peritoneal. Beneath this lies the **tunica adventitia,** composed of lax connective tissue.

The **middle** or **muscular coat** (*tunica muscularis*) consists of an **external longitudinal layer** (*stratum longitudinale*), and an internal **circular layer** (*stratum circulare*) of muscular fibres continuous with those of the uterus.

The **internal** or **mucous coat** (*tunica mucosa*) is continuous with the mucous lining of the uterus and, at the free extremity of the tube, with the peritoneum. It is thrown into **longitudinal folds** (*plicae tubariae*), which in the outer, larger part of the tube or **ampulla** (*plicae ampullares*) are much more extensive than in the narrow canal of the isthmus (*plicae isthmicae*). The lining epithelium is columnar and ciliated. This form of ephithelium is also found on the inner surface of the

[1] Spalteholz's Atlas. English edition by Barker.

fimbriae, while on the outer or serous surfaces of these processes the epithelium gradually merges into the endothelium of the peritoneum.

Vessels and Nerves.—The chief *artery* of the tube is the **tubal branch of the uterine artery** (*ramus tubarius*) (Fig. 1100). It also receives branches from the ovarian (Fig. 1100). Some of the **tubal veins** empty into the uterine veins, some into the ovarian veins. The **lymphatics** (Figs. 1101 and 1102) coming from the tube unite with the trunks coming from the uterus and ovary and terminate in the juxta-aortic glands. The **nerves** come from the same plexuses that send branches to the uterus and ovary.

The Epo-ophoron, Parovarium or **Organ of Rosenmüller** (Figs. 1094, 1095, and 1103) is placed in the mesosalpinx, between the ovary and tube. It consists of a number of epithelial-lined closed tubes. This structure can be readily seen if the mesosalpinx is stretched and held in front of the light. One of these tubes runs parallel to the Fallopian tube and is called **Gartner's duct** (*ductus epoophori longitudinalis*). A number of tubes (*ductuli transversi*) ascend from near the ovary and

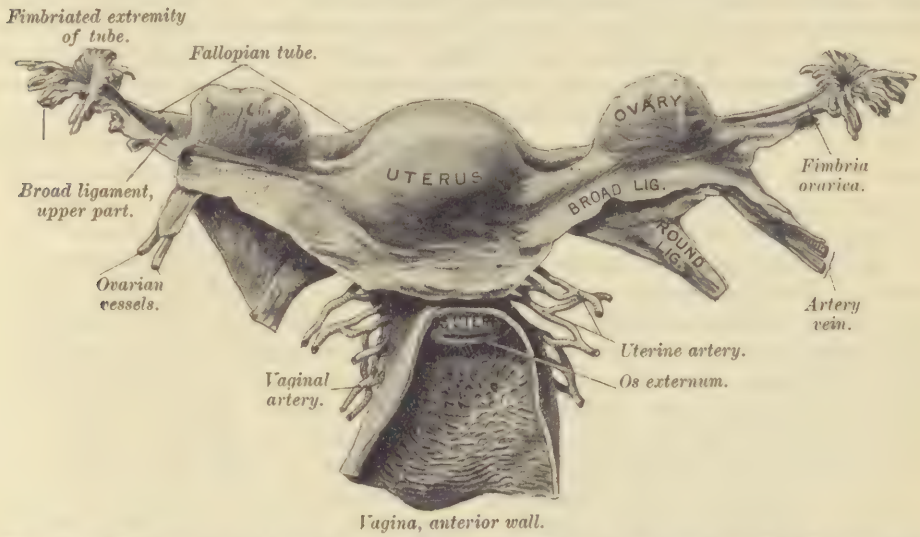

FIG. 1104.—The uterus and its appendages. Posterior view. The parts have been somewhat displaced from their proper position in the preparation of the specimen; thus the right ovary has been raised above the Fallopian tube, and the fimbriated extremities of the tubes have been turned upward and outward. (From a preparation in the Museum of the Royal College of Surgeons of England.)

each empties into Gärtner's duct at a right angle. Gärtner's duct is a portion of the Wolffian duct, which has persisted and is represented in the male by the canal of the epididymis. The tubules which join the duct "are derived from the mesonephros and represent the vasa efferentia and coni vasculosi of the testis, and probably also the ductuli aberrantes of the canal of the epididymis."[1]

The Paro-ophoron is within the mesosalpinx, but is nearer to the uterus than is the epo-ophoron. It consists of several small tubules, which can be seen in an adult only by the aid of a pocket lens. They are visible to the naked eye in a child at birth. It represents the organ of Giraldés in the male and is derived from the mesonephros.

THE OVARY (Figs. 1088, 1092, 1094, 1095, 1097, 1098, 1099, 1103, 1104).

The ovaries (*ovaria*), the **testes muliebres of Galen,** are two in number and are analogous to the testes in the male. They are oval-shaped bodies of an elongated

[1] Prof. Cunningham's Text-book of Human Anatomy.

form, flattened from above downward, situated one on each side of the uterus, in the posterior layer of the broad ligament behind and below the Fallopian tube. Each ovary is connected by its anterior straight margin to the broad ligament; by its lower extremity to the uterus by a proper ligament, the **ligament of the ovary** (*ligamentum ovarii proprium*) (Fig. 1103); and by its upper end to the fimbriated extremity of the Fallopian tube by the **ovarian fimbria** (*fimbria ovarica*) (Fig. 1103), its mesial and lateral surfaces and posterior convex border are free (Fig. 1104). The ovaries are of a grayish-pink color, and present either a smooth or a puckered, uneven surface. They are each about an inch and a half in length, three-quarters of an inch in width, and about a third of an inch thick, and weigh from one to two drachms.

The exact position of the ovary has been the subject of considerable difference of opinion, and writers are in conflict as to what is to be regarded as the normal position. The fact appears to be that the ovary is differently placed in different individuals. The two ovaries are seldom placed in absolutely identical positions. Hasse has described the ovary as being situated with its long axis transverse, or almost transverse, to the pelvic cavity. Schultze, on the other hand, believes that its long axis is antero-posterior. Kölliker asserts that the truth lies between these views, and that the ovary is placed obliquely in the pelvis, its long axis lying parallel to the external iliac vessels, with its surface directed inward and outward, and its convex free border upward. His has made some important observations on this subject, and his views are largely accepted. He teaches that the uterus rarely lies symmetrically in the middle of the pelvic cavity, but is generally inclined to one or other side, most frequently to the left, in the proportion of three to two. The position of the two ovaries varies according to the inclination of the uterus. When the uterus is inclined to the left, the ovary of this side lies with its long axis vertical and with one side closely applied to the outer wall of the pelvis, while the ovary of the opposite side, being dragged upon by the inclination of the uterus, lies obliquely, its outer extremity being retained in close apposition to the side of the pelvis by the infundibulo-pelvic ligament. When, on the other hand, the uterus is inclined to the right, the position of the two ovaries is exactly reversed, the right being vertical and the left oblique. In whichever position the ovary is placed, the Fallopian tube forms a loop around it, the uterine half ascending obliquely over it, and the outer half, including the dilated extremity, descending and bulging freely behind it. From this extremity the fimbriae pass upward on to the ovary and closely embrace it.

Waldeyer[1] states, as the result of the examination of fifty female subjects, ranging from early childhood to advanced age, that the ovary "lies on the lateral pelvic wall and vertically when the woman takes the erect posture." Its *tubal* extremity is near the external iliac vein; its uterine end is directed downward, while the Fallopian tube overlies it so as to cover it on its medial face entirely or nearly so. Its convex margin looks downward and backward toward the pelvic cavity and rectum, while its straight margin or hilum lies laterally on the pelvic wall attached to the mesosalpinx. He also finds that it lies in a distinct but shallow groove (*fossa ovarii*) limited above by the hypogastric artery and below by the ureter, in such a manner that the ureter lies along the convex margin of the ovary, and the hypogastric artery passes near the hilum or straight margin.

The ovary possesses two poles or extremities: (1) An **outer, superior** or **tubal extremity** (*extremitas tubaria ovarii*). (2) An **inner, inferior** or **uterine extremity** (*extremitas uterina ovarii*). The ovary has two surfaces, an **inner surface** (*facies medialis*), which is also upper; an **outer surface** (*facies lateralis*), which is also lower. The **posterior** or **free border** (*margo liber*) is markedly convex. The **anterior**

[1] Journal of Anatomy and Physiology, vol. xxxii.

border (*margo mesovaricus*) is almost straight and is narrow. The anterior border is not free, but is joined to the posterior layer of the broad ligament by a peritoneal fold known as the **mesovarium**. There is a groove in the anterior border called the **hilum** (*hilus ovarii*), through which vessels and nerves to pass, and emerge from the ovary.

Supports and Connections of the Ovary.

From its upper extremity a peritoneal fold is continuous with the peritoneum over the iliac vessels and Psoas muscle. It is called the **ovario-pelvic fold** or the **suspensory ligament** (*ligamentum suspensorium ovarii*) (Fig. 1088). It is in reality a portion of the broad ligament, and within it are the ovarian vessels and nerves. The vessels (Fig. 1104) and nerves go to the anterior border of the ovary and are surrounded by a peritoneal sheath derived from the posterior layer of the broad ligament; it is thus evident that the anterior border of the ovary is connected to the posterior portion of the broad ligament by a very short mesentery, the **mesovarium**[1] (Fig. 1098). The **ligament of the ovary** or **ovarian ligament** (Figs. 1088 and 1103) is a round, cord-like structure, composed chiefly of non-striated muscle-fibres, which passes between the two folds of the broad ligament from the lower extremity of the ovary to the lateral angle of the uterus. The **ovarian fimbria** (Fig. 1103), as previously stated, passes to the upper extremity of the ovary from the extremity of the Fallopian tube.

The Descent of the Ovary.

In the female there is a gubernaculum which effects a considerable change in the position of the ovary, though not so extensive a change as is effected upon the male testicle. The gubernaculum in the female, as it lies on either side in contact with the fundus of the uterus formed by the union of the Müllerian ducts, contracts adhesions to this organ and thus the ovary is prevented from descending below this level. The remains of the gubernaculum—that is to say, the part between the attachment of the cord to the uterus to its termination in the labium majus—ultimately forms the round ligament of the uterus. A pouch of peritoneum accompanies it along the inguinal canal, analogous to the funicular process in the male; it is called the **canal of Nuck**. In rare cases the gubernaculum fails to contract adhesions to the uterus, and then the ovary descends through the inguinal canal into the labium majus, extending down the canal of Nuck. Under these conditions, the position of the ovary resembles the position of the testicle in the male.

The Ovary at Different Ages.—The ovary of childhood is smooth and even. The rupture of Graafian follicles, repeated many times, causes the surface of the ovary to become pitted, puckered, fibrous, and uneven in old age. The surface of the ovary is grayish-red in color. The corpus luteum of a non-pregnant woman slowly degenerates and disappears. The corpus luteum of an impregnated woman enlarges during pregnancy.

Structure (Figs. 1098, 1099, 1105, and 1106).—The ovary consists of a number of **Graafian follicles** or **vesicles** embedded in the meshes of a stroma or framework, and invested by a serous covering derived from the peritoneum.

Serous Covering.—Though the investing membrane of the ovary is continuous with the peritoneum near the hilum of the ovary (the point of junction being indicated by a narrow white line), it differs essentially from the peritoneum, inasmuch as it is an epithelial structure and consists of a single layer of columnar epithelial cells, instead of the flattened endothelial cells of other parts of the

[1] Prof. Cunningham's Text-book of Anatomy.

membrane; this has been termed the **germinal epithelium of Waldeyer**, and gives to the surface of the ovary a dull-gray aspect instead of the shining smoothness of serous membranes generally.

Stroma.—The stroma is a peculiar soft tissue, abundantly supplied with blood-vessels, consisting for the most part of spindle-shaped cells, with a small amount of ordinary connective tissue. These cells have been regarded by some anatomists as unstriped muscle-cells, which, indeed, they most resemble (His); by others as connective-tissue cells (Waldeyer, Henle, and Kölliker). On the surface of the organ this tissue is much condensed, and forms a layer composed of short connective-tissue fibres, with fusiform cells between them. This was formerly regarded as a distinct fibrous covering, and was termed the **tunica albuginea**, but is nothing more than a condensed layer of the stroma of the ovary.

Graafian Follicles or Vesicles (*folliculi oophori vesiculori* [*Graafi*]) (Figs. 1105 and 1106).—Upon making a section of an ovary numerous round transparent vesicles of various sizes are to be seen; they are the **Graafian vesicles** or **ovisacs** containing the ova. Immediately beneath the superficial covering is a layer of stroma, in which are a large number of minute vesicles of uniform size, about $\frac{1}{100}$ of an inch in diameter. These are the Graafian vesicles in their earliest condition, and the layer where they are found has been termed the **cortical layer.** They are especially numerous in the ovary of the young child. After puberty and during the whole of the child-bearing period large and mature, or almost mature, Graafian vesicles are also found in the cortical layer in small numbers, and also **corpora lutea**, the remains of vesicles which have burst and are undergoing atrophy and absorption. Beneath this superficial stratum other large and mature Graafian vesicles are

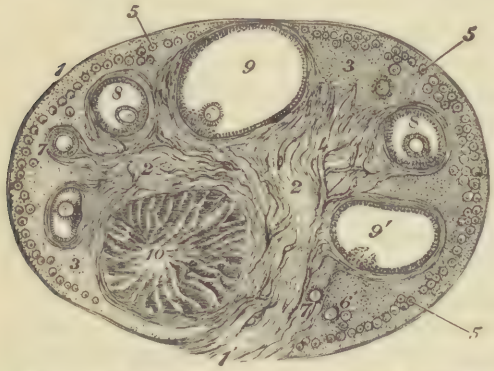

Fig. 1105. Section of the ovary. 1, outer covering; 1′, attached border; 2, central stroma; 3, peripheral stroma; 4, blood-vessels; 5, Graafian follicles in their earliest stage; 6, 7, 8, more advanced follicles; 9, an almost mature follicle; 9′, follicle from which the ovum has escaped; 10, corpus luteum. (After Schron.)

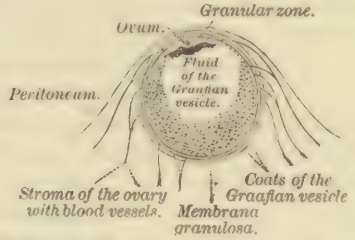

Fig. 1106.—Section of the Graafian vesicle. (After von Baer.)

found embedded in the ovarian stroma. These increase in size as they recede from the surface toward a highly vascular stroma in the centre of the organ, termed the **medullary substance** (*zona vasculosa* [*Waldeyeri*]). This stroma forms the tissue of the hilum by which the ovary is attached, and through which the blood-vessels enter; it does not contain any Graafian vesicles.

The larger Graafian follicles consist of an external fibro-vascular coat connected with the surrounding stroma of the ovary by a network of blood-vessels; and an internal coat, named the **ovicapsule**, which is lined by a layer of nucleated cells, called the **membrana granulosa.** The fluid contained in the interior of the vesicles is transparent and albuminous, and in it is suspended the ovum. In that part of the mature Graafian vesicle which is nearest the surface of the ovary the cells of the membrana granulosa are collected into a mass which projects into the cavity of the vesicle. This is termed the **discus proligerus**, and in this the ovum is embedded.

The ova are formed from the germinal epithelium on the surface of the ovary.

This becomes thickened, and in it are seen some cells which are larger and more rounded than the rest; these are termed the **primordial ova.** The germinal epithelium grows downward in the form of tubes or columns, termed the **egg tubes** of Pflüger, into the ovarian stroma, which grows outward between the tubes, and ultimately cuts them off from the germinal epithelium. These tubes are further subdivided into rounded **nests** or **groups** each containing a primordial ovum which undergoes further development and growth, while the surrounding cells of the nest form the epithelium of the Graafian follicle.

The development and maturation of the Graafian vesicles and ova continue uninterruptedly from puberty to the end of the fruitful period of woman's life, while their formation commences before birth. Before puberty the ovaries are small, the Graafian vesicles contained in them are disposed in a comparatively thick layer in the cortical substance; here they present the appearance of a large number of minute closed vesicles, constituting the early condition of the Graafian vesicle; many, however, never attain full development, but shrink and disappear. At puberty the ovaries enlarge and become more vascular, the Graafian vesicles are developed in greater abundance, and their ova are capable of fecundation.

Discharge of the Ovum.—The Graafian vesicles, after gradually approaching the surface of the ovary, burst; the ovum and fluid contents of the vesicles are liberated, and escape on the exterior of the ovary, passing thence into the Fallopian tube. This is effected either by application of the tube to the ovary, or by a curling upward of the fimbriated extremity, so that the ovum is caught as it falls.

In the fœtus the ovaries are situated, like the testes, in the lumbar region, near the kidneys. They may be distinguished from those bodies at an early period by their elongated and flattened form, and by their position, which is at first oblique and then nearly transverse. They gradually descend into the pelvis.

The Round Ligament (p. 1491).

Vessels and Nerves.—The **arteries of the ovaries** (Figs. 1100 and 1104) are the **ovarian** from the aorta, corresponding to the spermatic arteries in the male. The ovarian artery on each side enters the pelvis in the fold of broad ligament known as the suspensory ligament of the ovary and enters the attached border, or hilum, of the ovary. The ovarian vessels anastomose about the hilum with branches of the **uterine artery.** The **veins** follow the course of the arteries; they form a plexus near the ovary, the **pampiniform plexus,** corresponding to a like structure near the male testicle. The **lymphatics** (Figs. 1101 and 1102) terminate in the glands to the corresponding side of the aorta, and they anastomose in their course with trunks from the uterine fundus and Fallopian tube. The **nerves** come from the **ovarian plexus,** which is a continuation of the **renal plexus** along the ovarian artery, and from the **aortic plexus.**

Surgical Anatomy of the Appendages.—*Extra-uterine pregnancy* most commonly occurs in the ampulla of the tube. The product of the conception may escape through the ostium abdominale or the walls of the tube may rupture, a violent hemorrhage resulting.

Pelvic peritonitis is a not uncommon sequence of tubal disease. *Salpingitis* is inflammation of the mucous coat of the tube—*interstitial salpingitis* of the middle coat, *perisalpingitis* of the peritoneal coat.

If inflammation closes the uterine and the abdominal ends of the tube, mucus gathers and distends the tube (*hydrosalpinx*). If purulent matter gathers, the condition is known as *pyosalpinx*.

An ovary may fail to descend and remain well above the pelvic brim; it may *prolapse* into Douglas's pouch; it may enter the sac of a hernia; it may inflame; a *tumor* or *cyst* may arise from it. A *solid tumor* of the ovary may be a fibroma, a sarcoma, or a carcinoma. "Cysts may originate in any part of the tubo-ovarian structure; as the cortical, medullary, or parenchymatous portions of the ovary; in the structure between the tube and ovary known as the Rosenmüller organ or parovarian structures; and in the hydatid of Morgagni."[1] Cysts may be simple, proliferating, or dermoid; unilocular or multilocular. Glandular proliferous cysts, papillary pro-

[1] Text-book of Gynecology. By E. E. Montgomery.

liferous cysts, dermoid cysts, and parovarian cysts may attain a large or even an enormous size. The operation for the removal of an ovarian cyst is one of the most successful of the major procedures of surgery.

THE MAMMARY GLAND (MAMMA) (Figs. 1107, 1108, 1109, 1110).

The **breasts, mammary glands** or **mammae** secrete the milk, and are accessory glands of the generative system. They develop fully in the female, but remain permanently rudimentary in the male. There are two of these glands, and they are situated in the superficial fascia of the anterior portion of the thorax. Between the two glands and in front of the sternum is a groove, the **bosom.**

Description of a Well-developed Breast.—Each gland appears as a hemispherical body projecting from the front of the thorax beneath the skin and lying over a portion of the Pectoralis major muscle and a smaller portion of the Serratus magnus muscle. The hemispherical projection extends usually from the margin of the sternum to the axilla and from the level of the second rib to the level of the sixth rib, or from the third rib to the seventh rib, but this does not represent the real size of the gland. The gland is much larger than this, being rendered so by tails or prolongations of breast tissue, which will be described later (p. 1505).

The Nipple (*papilla mammae*) (Figs. 1107, 1108, 1109, and 1110).—The nipple projects from a little below and to the median side of the summit of the hemisphere at or above the level of the fifth rib, and is covered with thin skin. The right nipple may not exactly correspond in situation and direction to the left nipple. The nipple varies considerably in height and shape. In the virgin it is usually cylindrical and is directed forward and slightly upward and outward. The apex of the nipple is rendered rough by fissures (Fig. 1107), it exhibits a depression in which are the openings of the milk ducts (Fig. 1109), and its circumference is thrown into **concentric ridges** (Fig. 1109). The nipple is surrounded by a darker circular wrinkled area, the **areola** (*areola mammae*) (Figs. 1107 and 1108), in which are sweat-glands and on which are twelve or fifteen small rounded elevations. These elevations are caused by cutaneous sebaceous glands which in structure represent a transition between sebaceous and mammary glands. They are probably rudimentary portions of the mammary gland and are known as the **glands of Montgomery** (*glandulae areolares*) (Fig. 1109). The color of the nipple and areola varies with the complexion of the individual. In brunettes it is darker than in blondes. The usual color of the nipple in a young woman is rosy-pink, the areola being of a darker shade. During the early months of pregnancy the nipple and areola become dark brown in color, the areola becomes larger in circumference and the glands of Montgomery increase in size (Fig. 1110). The nipple contains non-striated muscle and mechanical irritation or sexual excitement makes it stiff and erect. The skin covering the breast is clear, soft, and delicate, and subcutaneous veins are often visible. The skin of the nipple and areola is particularly delicate.

Variations in the Mammae.—Before puberty the glands are small, of the infantile type, grow slowly, and differ but slightly from the male organs. The nipple is small and flat and pale. At puberty the increase in the size of the breast is rapid and considerable, due to growth of gland tissue and of subcutaneous fat. During pregnancy the breasts enlarge greatly and remain very large throughout lactation. This enlargement is due to new gland tissue and increased vascularity. Numerous blue veins are visible in the skin, the areola darkens, and the glands of Montgomery enlarge (Fig. 1110). During lactation the associated lymphatic glands may enlarge (A. Marmaduke Sheild). After the termination of lactation the breasts diminish in size. They do not become as small as the virgin breast, are apt to lose their hemispherical outlines, and cease to be soft. They droop as flaccid pendulous

masses, the subcutaneous fat is largely gone, and the outlines of the lobular breast tissue can be seen and felt. The nipple is long and hangs down like a teat. At the menopause the breast usually shrinks. In some cases, however, it actually increases in size. In such a case, although the gland atrophies, there is an extensive deposit of fat. In old age the glands undergo atrophy and largely disappear, the skin is flabby and thrown into wrinkles, and the breasts contain very little glandular structure, and are hard from the presence of fibrous tissue. The nipples become pigmented and corrugated. Women vary greatly in the development of the breasts. In some women they are large, firm, and well proportioned; in others they are small, flat, or atrophy occurs in the course of certain bodily diseases, as phthisis, and certain mental diseases, as melancholia. If the ovaries are ill-developed the breasts remain flat and small. In newly married women, even though pregnancy does not exist, the breasts often develop decidedly and rapidly. The outline and direction of the breast and also of the nipple may be altered by corsets. The left mamma is usually somewhat larger than the right.

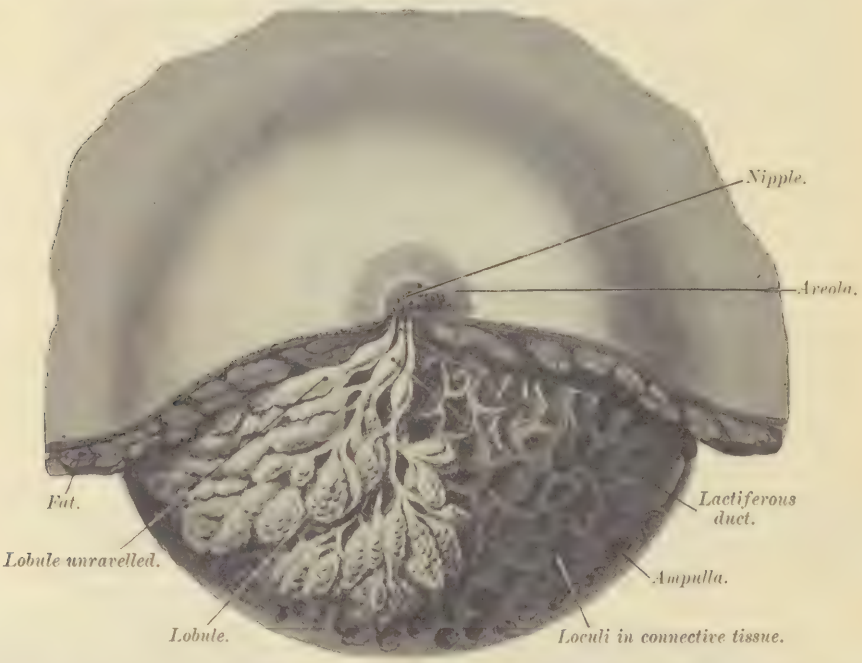

FIG. 1107.—Dissection of the lower half of the female breast during the period of lactation. (From Luschka.)

One gland or both glands may be entirely absent, the nipple being also absent. One or both glands may be absent, one or both nipples being present. When there is only one nipple, it is apt to be the left. The term **polymazia** (*mammae accessoriae muliebris*) means the presence of supernumerary breasts, with or without nipples. **Polythelia** means the presence of supernumerary nipples, the associated glandular structure being rudimentary. There may be one, two, or several supernumerary breasts, and when more than one exists, are usually asymmetrical. If one is functionally active, it enlarges during pregnancy and furnishes milk.

Supernumerary mammae may secrete milk or may be without function. The most common situation is on the part of the chest below and to the inner side of the normally placed gland. They may also exist in the axilla, the abdomen, the groin, the back, and the thigh. Many cases of supposed supernumerary glands have been really instances in which moles, warts, or sebaceous cysts have been mistaken for breast tissue, but some cases are undoubted.

Prolongations of Mammary Tissue.—As previously stated, the outlines of the breast are not regular, but here and there tails, prolongations, or cusps come off

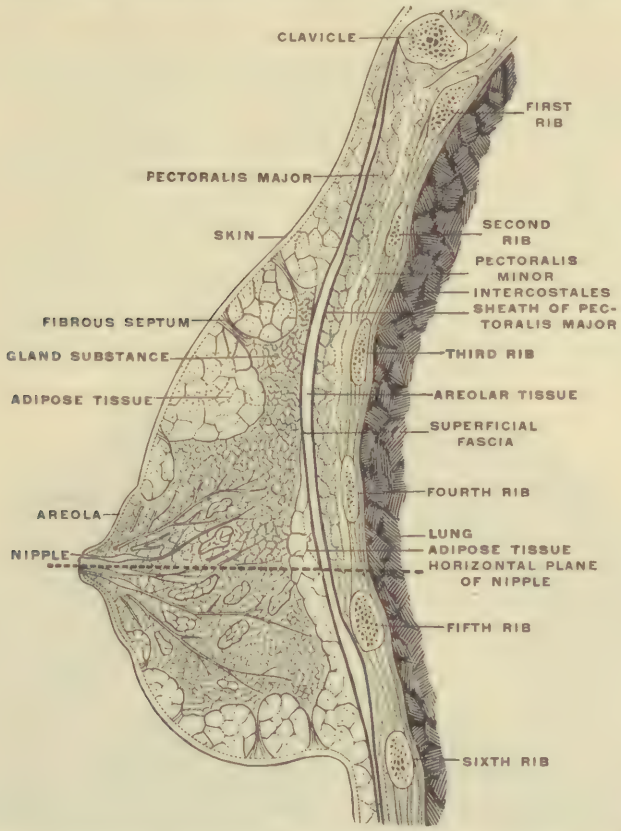

FIG. 1108.—Right breast in sagittal section, inner surface of outer segment. (Testut.)

from and are true portions of the gland. Two or even more prolongations pass to the edge of the sternum; others pass toward the axilla, the clavicle, and the origin

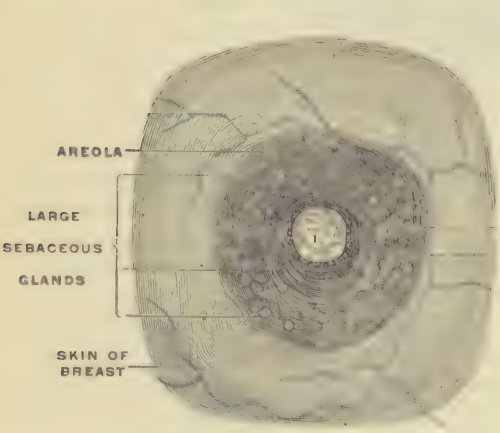

FIG. 1109.—Nipple and areola of a virgin. (Testut.)

FIG. 1110.—Nipple and areolae of a pregnant woman. (Testut.)

of the external oblique muscle from the ribs. Underneath the mammary gland prolongations of mammary tissue penetrate the pectoral fascia (Heidenhain).

If one of the glandular cusps is of considerable size it is called an **outlying lobule.**

Structure of Mammary Gland and Nipple (Figs. 1107 and 1108). — The **glands of the breast** (*corpus mammae*) rest by a smooth posterior surface upon the loose pectoral fascia, which fastens the breast to the muscle beneath, but so loosely that the breast is movable. The mamma consists of gland-tissue; of fibrous tissue, connecting its lobes, of fatty tissue in the intervals between the lobes, of retinacula, and of skin. The gland-tissue, when freed from fibrous tissue and fat, is of a pale reddish color, firm in texture, in general circular in form, with prolongations here and there, flattened from before backward, thicker in the centre than at the circumference, and presenting several inequalities on its surface, especially in front. On the anterior surface there are many irregular elevated processes with deep spaces between them. From the summits of the elevations connective-tissue strands (*retinacula cutis*) pass to the true skin. The glandular structure consists of numerous **lobes** (*lobi mammae*), and these are composed of **lobules** (*lobuli mammae*), connected together by areolar tissue, blood-vessels, and ducts. The smallest lobules consist of a cluster of rounded **alveoli** (Fig. 1107), which open into the smallest branches of the excretory ducts; these ducts, uniting, form larger ducts, which terminate in single canals. Each canal is called a **lactiferous, galactophorus** or **mammillary duct** (*ductus lactiferus*) (Fig. 1107). Each lobe possesses one lactiferous duct. This passes to the apex of the lobe and then into the nipple. The lactiferous ducts are white and cord-like, and contrast with the yellowish-red tissue of the gland itself. The number of excretory ducts varies from fifteen to twenty. They converge toward the areola, beneath which each duct forms a spindle-shaped dilatation, the **ampulla** (*sinus lactiferans*) (Fig. 1107). The ampullae serve as reservoirs for the milk. At the base of the nipple the ducts become contracted and pursue a straight course to its summit, perforating it by separate orifices considerably narrower than the ducts themselves. Each orifice (*porus lactiferus*) is the orifice of a tube which drains an individual lobe. The ducts are composed of areolar tissue, with longitudinal and transverse elastic fibres; muscular fibres are entirely absent; their mucous lining is continuous, at the point of the nipple, with the integument. The epithelium of the mammary gland differs according to the state of activity of the organ. In the gland of a woman who is not pregnant or nursing the alveoli are very small and solid, being filled with a mass of granular polyhedral cells. During pregnancy the alveoli enlarge and the cells undergo rapid multiplication. At the commencement of lactation the cells in the centre of an alveolus undergo fatty degeneration, and are eliminated in the first milk as **colostrum-corpuscles.** The peripheral cells of the alveolus remain, and form a single layer of granular, short columnar cells lining the limiting membrana propria. The single nucleus of each cell divides and forms two. In the protoplasm, especially in the end of the cells toward the alveolus, drops of fat appear, and the nucleus toward this end of the cell also becomes fatty.

The end of the cell toward the alveolus breaks down, and the liberated material constitutes "the albuminous ingredients of the milk, while the drops of fat become the milk-globules. The portion of the cell which remains forms new cytoplasm, and the same process is repeated over and over again. The cells also secrete water and the salts which are found in the milk."[1]

The **fibrous tissue** (Fig. 1108) invests the entire surface of the breast, and sends down septa between its lobes, connecting them together.

The **fatty tissue** (Figs. 1107 and 1108) surrounds the surface of the gland and occupies the interval between its lobes. It usually exists in considerable abun-

[1] Human Physiology. By Joseph Howard Raymond.

dance, and determines the form and size of the gland. There is no fat immediately beneath the areola and nipple.

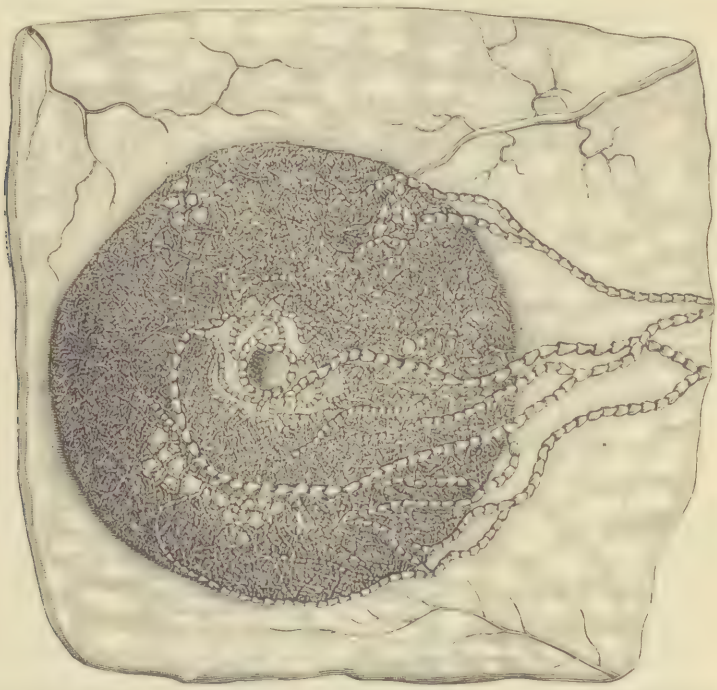

FIG. 1111.—The lymphatic vessels of the anterior surface of the breast; the subareolar plexus and the trunks which run from it. (Sappey.)

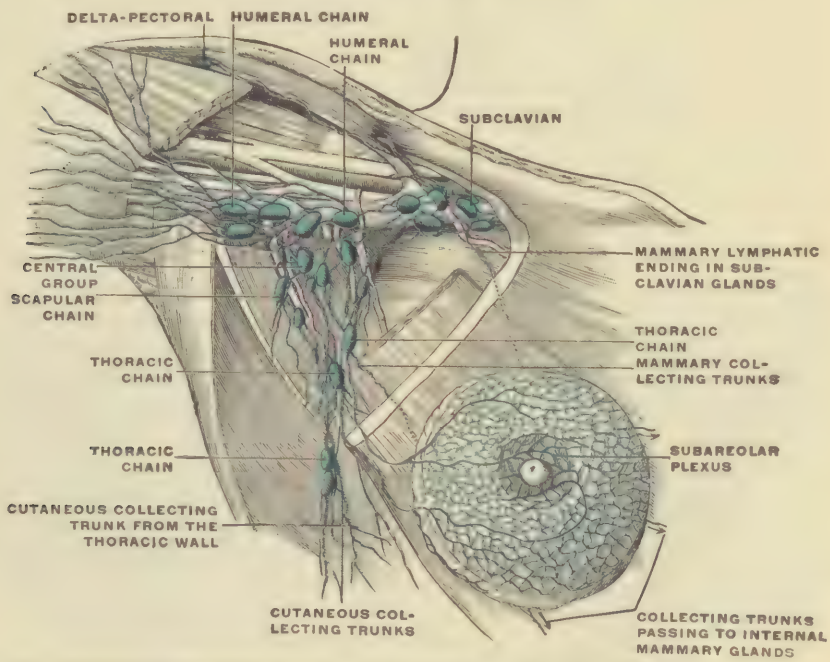

FIG. 1112.—Lymphatics of the breast and axillary glands. (Poirier and Charpy.)

Vessels and Nerves.—The arteries supplying the mammary gland are derived from the perforating branches of the internal mammary, long thoracic branches of the

axillary, and **branches from the intercostals.** The **veins** describe an anastomotic circle around the base of the nipple, called by Haller the **circulus venosus.** From this large branches transmit the blood to the circumference of the gland and end in the **axillary** and **internal mammary veins.** The **lymphatics** of the mammary gland (Figs. 1111 and 1112) and mammary region have been previously described (pp. 812, 813, and 814). The **nerves** are derived from the **fourth, fifth,** and **sixth intercostal nerves,** and **sympathetic filaments from the dorsal cord** pass to the breast along the branches of the intercostal nerves.

Surgical Anatomy.—Occasionally the mammary gland undergoes enormous *hypertrophy.* This may occur at any age, even in the virgin. The physiological enlargement of puberty may become excessive or the physiological enlargement of pregnancy and lactation may continue and increase after the termination of lactation. The chief elements in the enlargement are fat and connective tissue, and it is doubtful if there is extensive reproduction of glandular tissue.

Abscess of the breast may occur at any age, but is most common by far in nursing women. The portals are opened to infection by a crack in the nipple and bacteria are carried inward by the lymph-vessels. In some cases the pus gathers beneath the skin (*supra-mammary abscess*), in others in the breast tissue (*intra-mammary abscess*). In rare cases pus gathers beneath the breast (*retro-mammary abscess*). In intra-mammary abscess the pus burrows through the fibrous septa or fascia and forms numerous channels, and such a channel is constricted at the point where it passes through fascia or a fibrous septum, as an hour-glass is constricted.

In every patient suffering from abscess the nipple should be examined for a sore or crack, and the area when found should be treated antiseptically. A supra-mammary abscess should be opened by an incision radiating from the nipple.

In intra-mammary abscess follow the advice of Sheild: open the abscess by an incision radiating from the nipple, insert the index finger, and when possible pass it to the bottom of the abscess and carry the tip from the depths of the abscess to as near the surface as possible. At this point make a counter opening. The finger breaks down septa which cause constriction and thus converts the tracking sinuses into one large cavity.[1] Drain by tubes.

A retro-mammary abscess is opened by an incision, following the outline of the breast at the thoraco-mammary junction, the finger being pushed through the incision and up under the gland.

Tuberculosis of the breast may occur, and if it does, *cold abscess* is apt to form. The best treatment is removal of the gland and the associated lymph glands.

Chronic mastitis is a condition of mammary fibrosis, most common in neurotic single women, and apt to be associated with ovarian or uterine disease.

Malignant dermatitis or *Paget's disease* of the nipple is a chronic condition consisting of epithelial proliferation, induration, desquamation, and ulceration, and it is apt to be followed by epithelioma.

Chancre of the nipple is occasionally met with.

Secondary and *tertiary syphilitic lesions* are seen upon the skin of the breast, the nipple, and the areola.

Cysts and *tumors* are common in the breast.

There may be *cystic degeneration* of the gland in women near the menopause (*involution cysts*); a *lacteal cyst;* a *hydatid cyst;* an adenoma may become cystic.

The nipple may suffer from *epithelioma, myoma, myxoma, angioma, papilloma,* or *fibroma.*

The innocent tumors of the breast are *fibro-adenoma, cystic adenoma, myxoma,* and *angioma.*

The skin of the breast may suffer from any form of growth or cyst which could arise from the skin of another part. Malignant tumors of the glandular structure are ten times as frequent as innocent tumors. *Sarcoma* is rare; *carcinoma* is very common.

Carcinoma of the breast has occupied much of the attention of surgeons during recent years. The old operation was uniformly followed by recurrence. The modern radical operation has been evolved from the studies of Moore, the younger Gross, Heidenhain, Stiles, Banks, Halsted, and others. The modern operation always removes at least the skin and subcutaneous tissue over the hemispherical portion of the breast, the outlying lobules of the breast, the pectoral fascia, and the sternal portion of the great Pectoral muscle, the lymphatic tracts from the breast, the lymphatic glands and cellular tissue from the axilla, and from beneath the latissimus dorsi muscle. The pectoral fascia and the sternal portion of the great Pectoral muscle must come away in every case, because breast tissue may pass through the fascia. The entire breast must be removed, because even in a recent case the entire breast is regarded as infected. The clavicular portion of the great Pectoral muscle is anatomically distinct from the sternal portion and its removal is not imperative. Some operators remove the lesser Pectoral muscle. To leave it is of no value to the arm, and it frequently causes an annoying rigid band anterior to the axilla. To take it away

[1] Diseases of the Breast. By A. Marmaduke Sheild.

gives ready access to the axillary vessels at a desirable point above. The sheath of the axillary vein should be removed with the glands and cellular tissue of the axilla. The glands receiving lymph from the cancerous area must be removed, of course. In view of the fact that in an undetermined percentage of cases a lymph tract passes direct to the subclavian glands, it is evident that these glands may become infected by this route instead of, as is more usual, secondarily to axillary infection; hence it seems wiser in every case to remove the cellular tissue and glands from the subclavian triangle. All of these structures should be removed as one piece, in order to avoid cutting across lymph tracts and flooding the wound with carcinoma cells which might adhere, grow, and reproduce cancer.

Halsted's operation is the method adopted by most surgeons. The wound cannot be completely closed, and the raw spot is covered at once or later with Thiersch skin grafts. (For surgical considerations regarding the lymphatics in mammary carcinoma see page 814.)

The Male Breast (*mamma virilis*).—The male breast is a small flat structure, consisting chiefly of connective tissue, but containing some branched tubules. Under normal circumstances it remains permanently of the infantile type. It possesses a nipple which is much smaller than that of the female breast, and which usually lies over the fourth intercostal space, but may lie over the fourth or fifth rib. The nipples of the two sides are rarely placed quite symmetrically. Accessory glands and accessory nipples are as common among males as females. The male breast may exhibit some evidence of temporary functional activity at birth and at puberty. Cases have been recorded of actual lactation by the male breast.

Surgical Anatomy.—The male breasts may undergo enormous hypertrophy (*gynaecomazia*). In these cases the penis is often small and the testicles may be atrophied. The breasts may be absent in the male. Disease of the male breast is not nearly so frequent as disease of the female breast. The organ may be the seat of syphilis, tuberculosis, acute or chronic mastitis, abscess or tumor. A number of cases of cancer of the male breast have been recorded.

THE SURGICAL ANATOMY OF INGUINAL HERNIA AND FEMORAL HERNIA.

Dissection (Fig. 288).—For dissection of the parts concerned in inguinal hernia a male subject, free from fat, should always be selected. The body should be placed in the supine position, the abdomen and pelvis raised by means of blocks placed beneath them, and the lower extremities rotated outward, so as to make the parts as tense as possible. If the abdominal walls are flaccid, the cavity of the abdomen should be inflated through an aperture made at the umbilicus. An incision should be made along the middle line from a little below the umbilicus to the symphysis pubis, and continued along the front of the scrotum, and a second incision from the anterior superior spine of the ilium to just below the umbilicus. These incisions should divide the integument, and the triangular-shaped flap included between them should be reflected downward and outward, when the superficial fascia will be exposed.

The Superficial Fascia of the Abdomen (p. 433).—This, over the greater part of the abdominal wall, consists of a single layer of fascia, which contains a variable amount of fat; but as it approaches the groin it is easily divisible into two layers, between which are found the superficial vessels and nerves and the superficial inguinal lymphatic glands.

The **Superficial Layer of the Superficial Fascia** or the **Fascia of Camper** is thick, areolar in texture, containing adipose tissue in its meshes, the quantity of which varies in different subjects. Below, it passes over Poupart's ligament, and is continuous with the outer layer of the superficial fascia of the thigh. In the male this fascia is continued over the penis and over the outer surface of the cord to the scrotum, where it helps to form the dartos. As it passes to the penis, and over the cord to the scrotum it changes its character, becoming thin, destitute of adipose tissue, and of a pale reddish color; and in the scrotum it acquires some involuntary muscular fibres. From the scrotum it may be traced backward, to be continuous with the superficial fascia of the perinæum. In the female this fascia is continued into the labia majora.

The **hypogastric branch of the ilio-hypogastric nerve** perforates the aponeurosis of the External oblique muscle about an inch above and a little to the outer side of the external abdominal ring, and is distributed to the integument of the hypogastric region.

The **ilio-inguinal nerve** escapes at the external abdominal ring, and is distributed to the integument of the upper and inner part of the thigh, to the scrotum in the male and to the labium in the female.

The **superficial epigastric artery** arises from the femoral about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on to the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal lymphatic glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric and internal mammary arteries.

The **superficial circumflex iliac artery**, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the superficial inguinal lymphatic glands, the superficial fascia, and

the integument, anastomosing with the deep circumflex iliac and with the gluteal and external circumflex arteries.

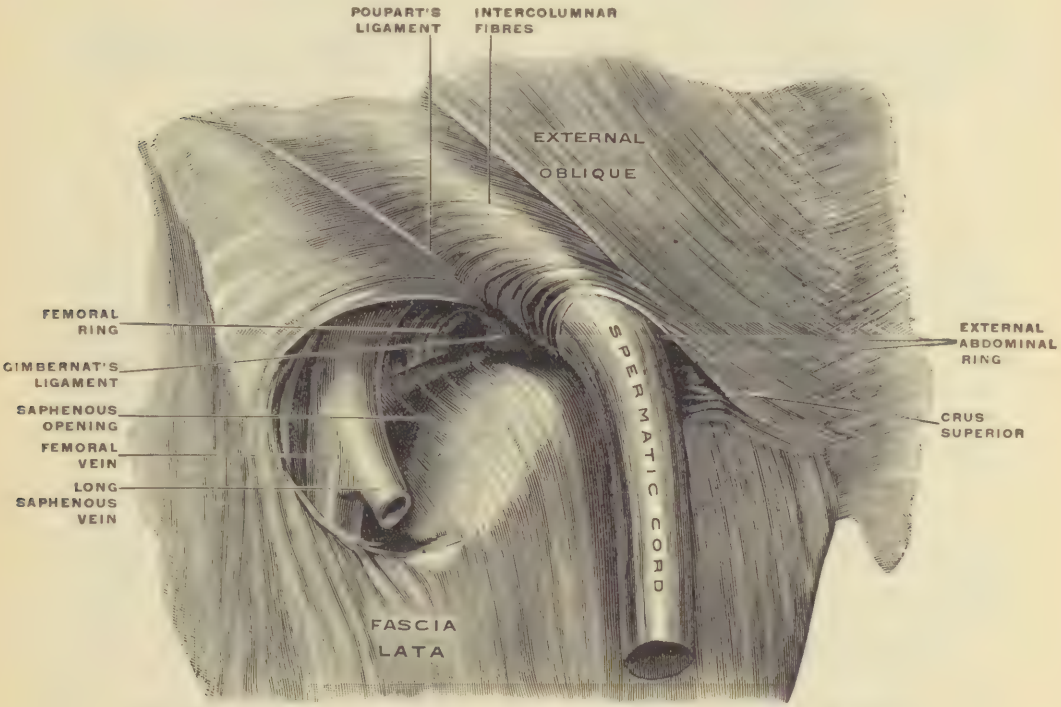

FIG. 1113.—Right external abdominal ring and saphenous opening in the male. (Spalteholz.)

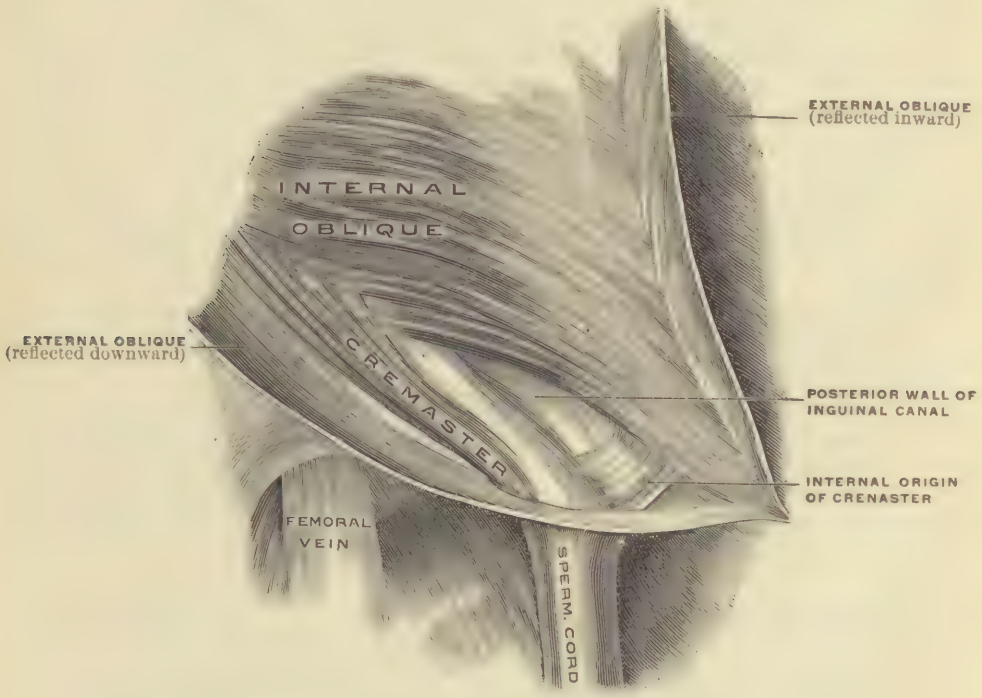

FIG. 1114.—Right inguinal canal in the male. Second layer viewed from in front. (Spalteholz.)

The **superficial external pudic (superior) artery** arises from the inner side of the femoral artery close to the preceding vessels, and, after passing through the saphenous opening, courses inward across the spermatic cord, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium in the female, anastomosing with branches of the internal pudic.

The Superficial Veins.—The veins accompanying these superficial vessels are usually much larger than the arteries; they terminate in the internal saphenous vein.

The **superficial inguinal lymphatic glands** are placed immediately beneath the integument, are of large size, and vary from ten to twenty in number (p. 793).

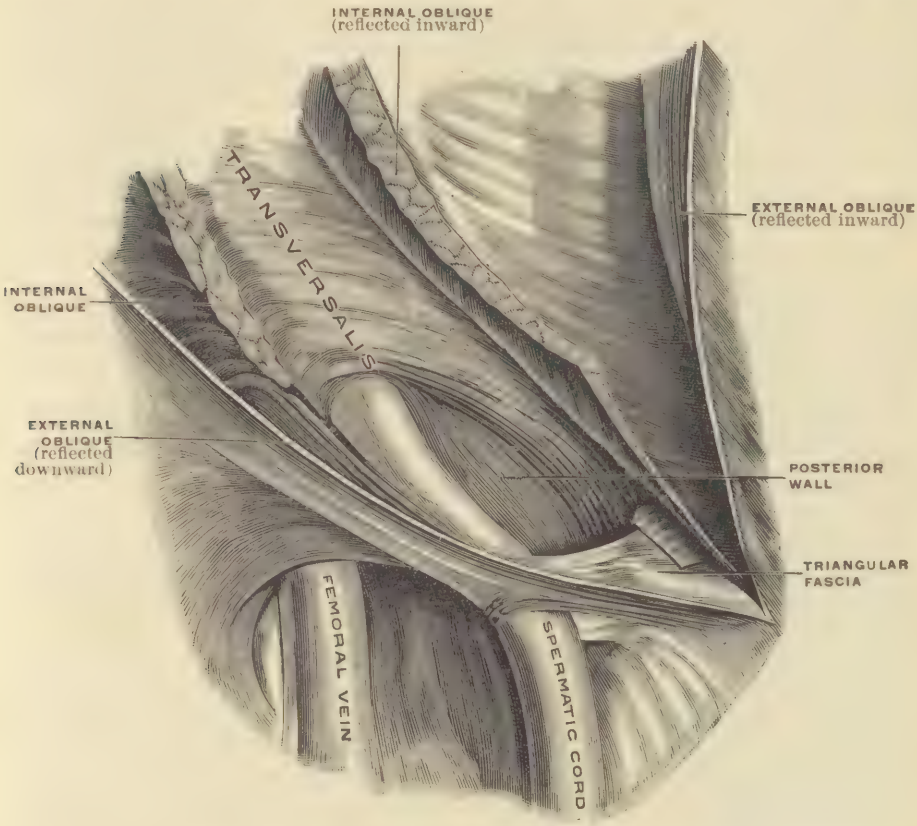

FIG. 1115.—The right inguinal canal in the male. Third layer viewed from in front. (Spalteholz.)

The **Deep Layer of the Superficial Fascia**, the **Fascia of Scarpa** or the **Fascia of Cooper** (p. 433) is thinner and more membranous in character than the superficial layer. In the middle line it is intimately adherent to the linea alba; above, it is continuous with the superficial fascia over the rest of the trunk; below, it blends with the fascia lata of the thigh a little below Poupart's ligament; below and internally, in the male, it is continued over the penis and over the outer surface of the cord to the scrotum, where it helps to form the dartos. From the scrotum it may be traced backward to be continuous with the base of the triangular ligament of the urethra. In the female it is continuous with the labia majora.

The scrotum is a cutaneous pouch which contains the testes and part of the spermatic cords, and into which an inguinal hernia frequently descends.

The Aponeurosis of the External Oblique Muscle (Fig. 1113).—This is a thin but strong membranous aponeurosis, the fibres of which are directed obliquely downward and inward. That portion of the aponeurosis which extends between

the anterior superior spine of the ilium and the spine of the os pubis is a broad band, folded inward and continuous below with the fascia lata; it is called **Poupart's ligament** (Figs. 289, 1113, 1116, 1117, 1119, 1124, 1125). The portion which is reflected from Poupart's ligament at the spine of the os pubis, along the pectineal line, is called **Gimbernat's ligament** (Fig. 297, 340, 1113, 1124, 1125). A thin fibrous band extends from the inner end of Poupart's ligament and Gimbernat's ligament upward and inward behind the inner pillar of the external ring to the anterior layer of the rectus sheath. The fibres diverge as they ascend. This band is known as the **triangular fascia** or **Colles's fascia** or the **triangular ligament of Colles** (Figs. 1115 and 1119).

The External or Superficial Abdominal Ring (*annulus inguinalis subcutaneus*) (Figs. 289 and 1113).—Just above and to the outer side of the crest of the os pubis an interval is seen in the aponeurosis of the External oblique, called the **external abdominal ring**. This aperture is oblique in direction, somewhat triangular in form, and corresponds with the course of the fibres of the aponeurosis. It usually measures from base to apex about an inch, and transversely about half an inch. It is bounded below by the crest of the os pubis; above, by a series of curved fibres, the **intercolumnar fibres**, which pass across the upper angle of the ring, so as to increase its strength; and on either side by the margins of the opening in the aponeurosis, which are called the **columns** or **pillars of the ring**.

The **External Pillar**, which at the same time is **inferior** (*crus inferius*), from the obliquity of its direction, is the stronger; it is formed by that portion of Poupart's ligament which is inserted into the spine of the os pubis; it is curved, so as to form a kind of groove, upon which the spermatic cord rests.

The **Internal** or **Superior Pillar** (*crus superius*) is a broad, thin, flat band, which is attached to the front of the body of the os pubis, interlacing with its fellow of the opposite side in front of the symphysis pubis, that of the right side being superficial.

The external abdominal ring gives passage to the spermatic cord in the male and round ligament in the female; it is much larger in men than in women, on account of the large size of the spermatic cord, hence the great frequency of inguinal hernia in men.

The **Intercolumnar Fibres** (*fibrae intercrurales*) (Fig. 1113) are a series of curved tendinous fibres which arch across the lower part of the aponeurosis of the External oblique. They have received their name from stretching across between the two pillars of the external ring; they increase the strength of the lower part of the aponeurosis and prevent the divergence of the pillars from one another. They are thickest below, where they arise from Poupart's ligament, and they are inserted into the linea alba, describing a curve, with the convexity downward. They are much thicker and stronger at the outer angle of the external ring than internally, and are more strongly developed in the male than in the female. These intercolumnar fibres, as they pass across the external abdominal ring, are themselves connected together by delicate fibrous tissue, thus forming a fascia which, as it is attached to the pillars of the ring, covers it in, and is called the **intercolumnar fascia**. This intercolumnar fascia is continued downward as a tubular prolongation around the outer surface of the cord and testis, and encloses them in a distinct sheath; hence, it is also called the **external spermatic fascia**. The sac of an inguinal hernia in passing through the external abdominal ring receives an investment from the intercolumnar fascia.

If the finger is introduced a short distance into the external ring and the limb is then extended and rotated outward, the aponeurosis of the External oblique, together with the iliac portion of the fascia lata, will be felt to become tense and the external ring much contracted; if the limb is, on the contrary, flexed upon the pelvis and rotated inward, this aponeurosis will become lax, and the external ring

sufficiently enlarged to admit the finger with comparative ease; hence the patient should always be put in the latter position when the taxis is applied for the reduction of an inguinal hernia, in order that the abdominal walls may be relaxed as much as possible.

The aponeurosis of the External oblique should be removed by dividing it across in the same direction as the external incisions, and reflecting it downward and outward; great care is requisite in separating it from the aponeurosis of the muscle beneath. The lower part of the Internal oblique and the Cremaster are then exposed, together with the inguinal canal, which contains the spermatic cord (Fig. 1116). The mode of insertion of Poupart's and Gimbernat's ligaments into the os pubis should also be examined.

Poupart's Ligament (*ligamentum inguinale* [*Pouparti*]) (Figs. 289, 1113, 1116, 1117, 1119, 1124, and 1125) or the crural arch is the lower border of the aponeurosis of the External oblique muscle, which extends from the anterior superior spine of the ilium to the spine of the os pubis. From this latter point it is reflected outward to be attached to the pectineal line for about half an inch, forming Gimbernat's ligament. Its general direction is curved downward toward the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction; its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord.

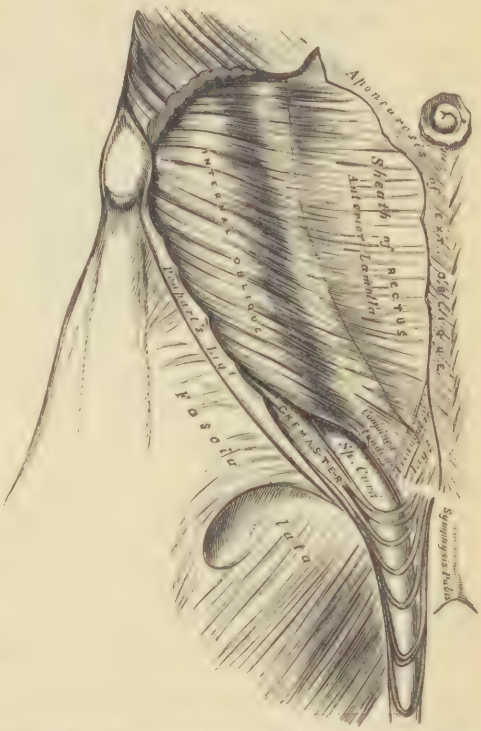

FIG. 1115. Inguinal hernia. Dissection showing the Internal oblique and Cremaster.

Gimbernat's Ligament (*ligamentum lacunare* [*Gimbernati*]) (Figs. 289, 297, 340, 1113, 1124, and 1125) is that portion of the aponeurosis of the External oblique muscle which is reflected upward and outward from the spine of the os pubis to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form, with the base directed outward. Its base or outer margin is concave, thin, and sharp, and lies in contact with the femoral sheath, forming the inner boundary of the femoral ring (Fig. 1124). Its apex corresponds to the spine of the os pubis. Its posterior margin is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its anterior margin is continuous with Poupart's ligament.

The **Triangular Fascia of the Abdomen, Colles's Fascia** or the **Triangular Ligament of Colles** (*ligamentum inguinale reflexum* [*Collesi*]) (Fig. 1115, 1116, and 1119) is a band of tendinous fibres, of a triangular shape, which is attached by its apex to the inner end of Poupart's ligament and to Gimbernat's ligament. It passes inward beneath the spermatic cord, and expands into a somewhat fan-shaped fascia, lying behind the inner pillar of the external abdominal ring and in front of the conjoined tendon, and interlaces with the ligament of the other side at the linea alba in the anterior layer of the sheath of the Rectus muscle.

The Ligament of Cooper.—See Fig. 297 and p. 437.

The **Internal Oblique Muscle** (Figs. 1114, 1115, and 1116) has been previously described (p. 437). The part which is now exposed is partly muscular and partly tendinous in structure. Those fibres which arise from Poupart's ligament, few in number and paler in color than the rest, arch downward and inward across the spermatic cord, and, becoming tendinous, are inserted, conjointly with those of the Transversalis, into the crest of the os pubis and pectineal line, forming what is known as the **conjoined tendon** of the Internal oblique and Transversalis (Figs. 1116 and 1117). This tendon is inserted immediately behind the inguinal canal and external abdominal ring, serving to protect what would otherwise be a weak point in the abdominal wall. The conjoined tendon is sometimes divided into an outer and an inner portion, the former being called the **ligament of Hesselbach** (*ligamentum interfoveolare*) (Fig. 292), and the latter the **ligament of Henle** (Fig. 292). Sometimes the conjoined tendon is insufficient to resist the pressure from within, and is carried forward in front of the protrusion through the external ring, forming one of the coverings of direct inguinal hernia, or the hernia forces its way through the fibres of the conjoined tendon.

The **Cremaster** (Figs. 1114 and 1116) is derived from the lower margin of the Internal oblique, of which muscle it is in reality a portion. It is a thin muscular layer composed of a number of fasciculi. It arises by a thick external bundle of fibres from the upper portion of Poupart's ligament, being connected with the Internal oblique muscle and also occasionally with the Transversalis. It arises also by a thin inner bundle of fibres from the anterior layer of the rectus sheath.

The thick bundle of origin is on the lateral surface; the thin bundle is on the medial surface of the spermatic cord. The Cremaster passes along with the spermatic cord, and descends with it through the external ring. Upon the front and sides of the cord both bundles spread out upon the vaginal tunic of the testicle and epididymis, and form a series of loops which differ in thickness and length in different subjects. These loops are united together by areolar tissue, and form a thin covering over the cord and testis, the **cremasteric fascia** (*fascia cremasterica*).

It will be observed that the Cremaster is a separated portion of the Internal oblique. This fact affords an easy explanation of the manner in which the testicle and cord are invested by this muscle. At an early period of fœtal life the testis is placed at the lower and back part of the abdominal cavity, but during its descent toward the scrotum, which takes place before birth, it passes beneath the arched border of the Internal oblique. In its passage beneath this muscle some fibres are derived from its lower part, which accompany the testicle and cord into the scrotum.

It occasionally happens that the loops of the Cremaster surround the cord, some lying behind as well as in front. It is probable that under these circumstances the testis in its descent passes through, instead of beneath, the fibres of the Internal oblique.

In the descent of an oblique inguinal hernia, which takes the same course as the spermatic cord, the Cremaster muscle forms one of its coverings. This muscle becomes largely developed in cases of hydrocele and large old scrotal herniæ. No such muscle exists in the female, but an analogous structure is developed in those cases where an oblique inguinal hernia descends beneath the margin of the Internal oblique.

The Internal oblique should be detached from Poupart's ligament, separated from the Transversalis to the same extent as in the previous incisions, and reflected inward on to the sheath of the Rectus (Fig. 1117). The deep circumflex iliac vessels, which lie between these two muscles, form a valuable guide to their separation.

The **Transversalis Muscle** (Figs. 1115 and 1117) has been previously described (p. 442). The part which is now exposed is partly muscular and partly tendinous in structure; it arises from the outer third of Poupart's ligament, its fibres curve downward and inward, and are inserted, together with those of the Internal oblique, into the lower part of the linea alba, into the crest of the os pubis and the pectineal line, forming what is known as the conjoined tendon of the Internal oblique and Transversalis (Figs. 1116 and 1117). The **falx aponeurotica [inguinalis]** is a collection of fibres of tendinous consistence in the inner side of the Transversalis insertion. Between the lower border of this muscle and Poupart's ligament a space is left in which is seen the transversalis fascia.

The **Inguinal** or **Spermatic Canal** (*canalis inguinalis*) (Figs. 1114, 1115, and 1117) contains the spermatic cord in the male and the round ligament in the female. It is an oblique canal, about an inch and a half in length, directed downward and inward and placed parallel with, and a little above, Poupart's ligament. It commences above at the internal or deep abdominal ring, which is the point where

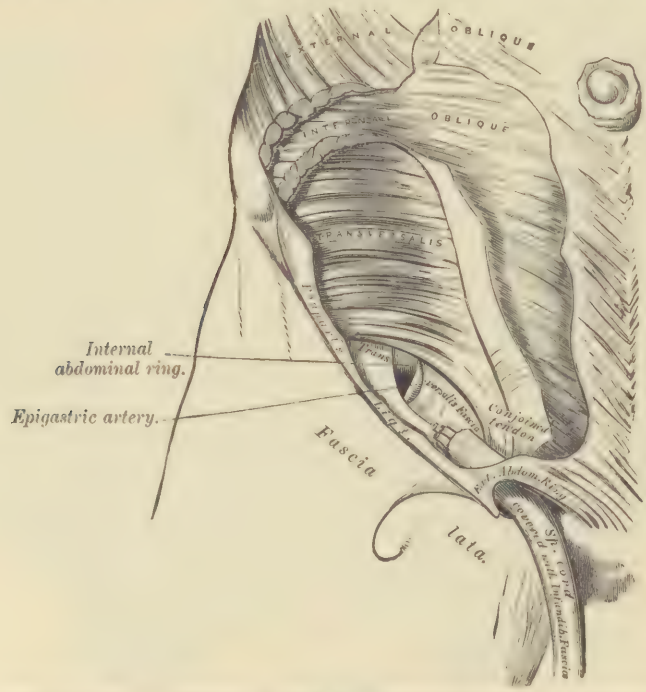

FIG. 1117.—Inguinal hernia. Dissection showing the Transversalis muscle, the transversalis fascia, and the internal abdominal ring.

the cord enters the inguinal canal, and terminates below at the external or superficial ring. It is bounded, *in front*, by the integument and superficial fascia, by the aponeurosis of the External oblique throughout its whole length, and by the Internal oblique for its outer third; *behind*, by the triangular fascia, the conjoined tendon of the Internal oblique and Transversalis, transversalis fascia, and the subperitoneal fat and peritoneum; *above*, by the arched fibres of the Internal oblique and Transversalis; *below*, by the union of the transversalis fascia with Poupart's ligament. That form of hernia in which the intestine follows the course of the spermatic cord along the inguinal canal is called **oblique inguinal hernia.**

On the posterior wall of the inguinal canal is seen the band of fibres known as the **ligament of Hesselbach** (*ligamentum interfoveolare* [*Hesselbachi*]) (Fig. 292). It is placed in front of the deep epigastric artery. The fibres come from the external portion of the lower fibres of the conjoined tendon (Fig. 1116) and pass

downward for a distance, some of them then passing outward and upward, some of them downward and inward to the inner surface of Poupart's ligament.

The **Transversalis Fascia** (Figs. 297, 1117, and 1125) is a thin aponeurotic membrane which lies between the inner surface of the Transversalis muscle and the peritoneum. It forms part of the general layer of fascia which lines the interior of the abdominal and pelvic cavities, and is directly continuous with the iliac and pelvic fasciae.

In the inguinal region the transversalis fascia is thick and dense in structure, and joined by fibres from the aponeurosis of the Transversalis muscle; but it becomes thin and cellular as it ascends to the Diaphragm. Below, it has the following attachments; external to the femoral vessels it is connected to the posterior margin of Poupart's ligament, and is there continuous with the iliac fascia. Internal to the vessels it is thin, and attached to the os pubis and pectineal line behind the conjoined tendon, with which it is united; and, corresponding to the points where the femoral vessels pass into the thigh, this fascia descends in front of them, forming the anterior wall of the femoral sheath. The spermatic cord in the male and the round ligament in the female pass through this fascia; the point where they pass through is called the internal or deep abdominal ring. This opening is not visible externally, owing to a prolongation of the transversalis fascia on the structures forming the infundibuliform fascia.

The **Internal** or **Deep Abdominal Ring** (*annulus inguinalis abdominalis*) (Figs. 297 and 1117) is situated in the transversalis fascia, midway between the anterior superior spine of the ilium and symphysis pubis, and about half an inch above Poupart's ligament. It is of an oval form, its long diameter being directed upward and downward; it varies in size in different subjects, and is much larger in the male than in the female. It is bounded above and externally by the arched fibres of the Transversalis muscle, below and internally by the deep epigastric vessels. It transmits the spermatic cord in the male and the round ligament in the female. From its circumference, a thin, funnel-shaped membrane, the **infundibuliform fascia,** is continued around the cord and testis, enclosing them in a distinct pouch (Fig. 1117). When the sac of an oblique inguinal hernia passes through the internal or deep abdominal ring, the infundibuliform fascia constitutes one of its coverings.

The Subperitoneal Areolar Tissue or the Fascia Propria of Cooper.—Between the transversalis fascia and the peritoneum is a quantity of loose areolar tissue. In some subjects it is of considerable thickness and loaded with adipose tissue. Opposite the internal ring it is continued around the surface of the cord, forming a loose sheath for it.

The **Deep Epigastic Artery** (Figs. 292 and 1118) *arises* from the external iliac artery a few lines above Poupart's ligament. It at first descends to reach this ligament, and then ascends obliquely along the inner margin of the internal or deep abdominal ring, lying between the transversalis fascia and the peritoneum, and passing upward pierces the transversalis fascia and enters the sheath of the Rectus muscle by passing over the **semilunar fold of Douglas.** Consequently the deep epigastric artery bears a very important relation to the internal abdominal ring as it passes obliquely upward and inward from its origin from the external iliac. In this part of its course it lies along the lower and inner margin of the internal ring and beneath the commencement of the spermatic cord. At its commencement it is crossed by the vas deferens in the male and by the round ligament in the female.

The **Peritoneum** (Fig. 1118), corresponding to the inner surface of the internal ring, presents a well-marked depression, the depth of which varies in different subjects. A thin fibrous band is continued from it along the front of the cord for a variable distance, and becomes ultimately lost, the **ligament of Cloquet.** This is the remains of the pouch of peritoneum which, in the fœtus, precedes

the cord and testis into the scrotum, the obliteration of which commences soon after birth. In some cases the fibrous band can only be traced a short distance, but occasionally it may be followed, as a fine cord, as far as the upper end of the **tunica vaginalis**. Sometimes the tube of peritoneum is closed only at intervals and presents a sacculated appearance, or a single pouch may extend along the whole length of the cord, which may be closed above, or the pouch may be directly continuous with the peritoneum by an opening at its upper part.

In the female fœtus the peritoneum is also prolonged in the form of a tubular process for a short distance into the inguinal canal. This process is called the **canal of Nuck**. It is generally obliterated in the adult, but sometimes it remains pervious even in advanced life.

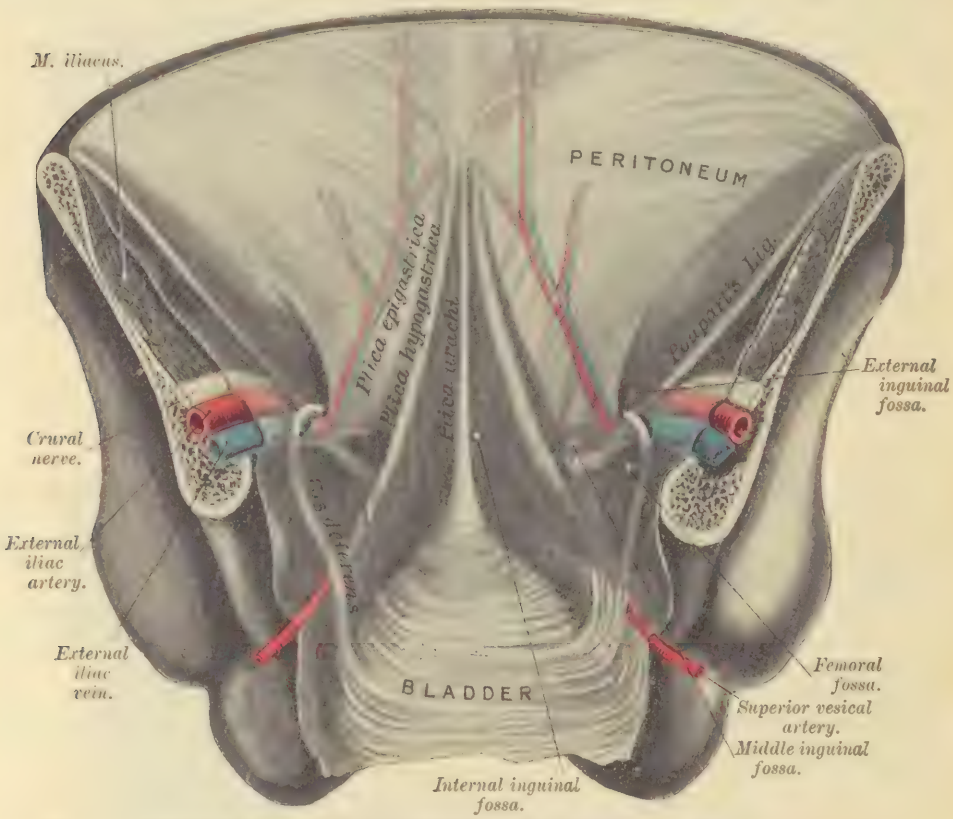

FIG. 1118.—Posterior view of the anterior abdominal wall in its lower half. The peritoneum is in place, and the various cords are shining through. (After Joessel.)

In order to understand the relation of the peritoneum to inguinal hernia, it is necessary to view the anterior abdominal wall from its internal aspect, when it will be seen as shown in Fig. 1118. Between the upper margin of the front of the pelvis and the umbilicus, the peritoneum, when viewed from behind, will be seen to be raised into five vertical folds, with intervening depressions, by more or less prominent bands which converge to the umbilicus. One of these is situated in the median line, and is caused by the urachus, the remnant of the allantois; it extends from the summit of the bladder to the umbilicus. The fold of peritoneum covering it is known as the **fold of the urachus** or the **plica urachi** (*plica umbilicalis media*). On either side of this is a prominent band, caused by the obliterated hypogastric artery, which extends from the side of the bladder obliquely upward and inward to the umbilicus. This is covered by a fold of peritoneum which is known as the

hypogastric fold or the **plica hypogastrica** (*plica umbilicalis lateralis*). To either side of these three cords is the deep epigastric artery, which ascends obliquely upward and inward from a point midway between the symphysis pubis and the anterior superior spine of the ilium to the **semilunar fold of Douglas**, in front of which it disappears. It is covered by a fold of peritoneum which is known as the **plica epigastrica.** Between these raised folds are depressions of the peritoneum, constituting so-called fossae. The most internal, between the plica urachi and the plica hypogastrica, is known as the **internal inguinal fossa** (*fovea supravesicalis*). The middle one is situated between the plica hypogastrica and the plica epigastrica, and is termed the **middle inguinal fossa** (*fovea inguinalis mesialis*). The external one is external to the plica epigastrica, and is known as the **external inguinal fossa** (*fovea inguinalis lateralis*). Occasionally the deep epigastric artery corresponds in position to the obliterated hypogastric artery, and then there is but one fold on each side of the middle line, and the two external fossae are merged into one. In the usual condition of the parts the floor of the external inguinal fossa corresponds to the internal abdominal ring, and into this fossa an oblique inguinal hernia descends. To the inner side of the plica epigastrica are the two internal fossae, and through either of these a direct hernia may descend, as will be explained in the sequel (p. 1523). The whole of this space, that is to say, the space between the deep epigastric artery, the margin of the Rectus and Poupart's ligament, is commonly known as **Hesselbach's triangle.** These three depressions or fossae are situated above the level of Poupart's ligament, and in addition to them is another below the ligament, corresponding to the position of the femoral ring, and into which a femoral hernia descends.

INGUINAL HERNIA.

Inguinal hernia is that form of protrusion which makes its way through the abdomen in the inguinal region.

There are two principal varieties of inguinal hernia—**external** or **oblique**, and **internal** or **direct.**

External or oblique inguinal hernia, the more frequent of the two, takes the same course as the spermatic cord. It is called *external* from the neck of the sac being on the outer or iliac side of the deep epigastric artery.

Internal or direct inguinal hernia does not follow the same course as the cord, but protrudes through the abdominal wall on the inner or pubic side of the deep epigastric artery.

Oblique Inguinal Hernia.

In oblique inguinal hernia (Fig. 1118) the intestine or omentum escapes from the abdominal cavity at the internal ring. Before it is a pouch of peritoneum, which forms the hernial sac (Fig. 1119, *A*). This pouch of peritoneum is invested by the **subserous areolar tissue**, and is enclosed in the **infundibuliform process of the transversalis fascia**, which it receives as it enters the inguinal canal. In passing along the inguinal canal the hernia displaces upward the arched fibres of the Transversalis and Internal oblique muscles, and is imperfectly surrounded by the fibres of the Cremaster muscles, the coat being completed by the **cremasteric fascia.** It then passes along the front of the cord, and escapes from the inguinal canal at the external ring, receiving an investment from the **intercolumnar fascia.** Lastly, it descends into the scrotum, receiving coverings from the **superficial fascia** and the **integument.**

The coverings of this form of hernia, after it has passed through the external ring, are, from without inward, the integument, superficial fascia, intercolumnar

fascia, Cremaster muscle and fascia, infundibuliform fascia, subserous areolar tissue, and peritoneum.

This form of hernia lies in front of the vessels of the spermatic cord and seldom extends below the testis, on account of the intimate adhesion of the coverings of the cord to the tunica vaginalis (Fig. 1120, *A*).

The **seat of stricture** in a strangulated oblique inguinal hernia is either at the external ring, in the inguinal canal, caused by the fibres of the Internal oblique or Transversalis; or at the internal ring, most frequently in the latter situation. If it is situated at the external ring, the division of a few fibres at one point of its circumference is all that is necessary for the replacement of the hernia. If in the inguinal canal or at the internal ring, it may be necessary to divide the

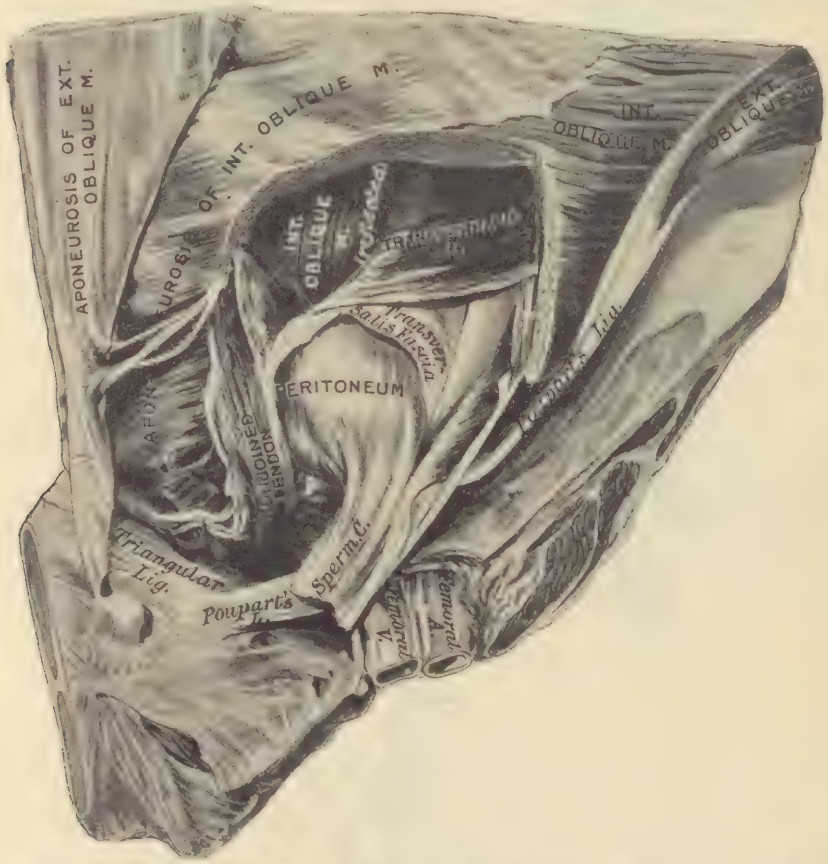

FIG. 1119.—Oblique inguinal hernia, showing its various coverings. (From a preparation in the Museum of the Royal College of Surgeons.)

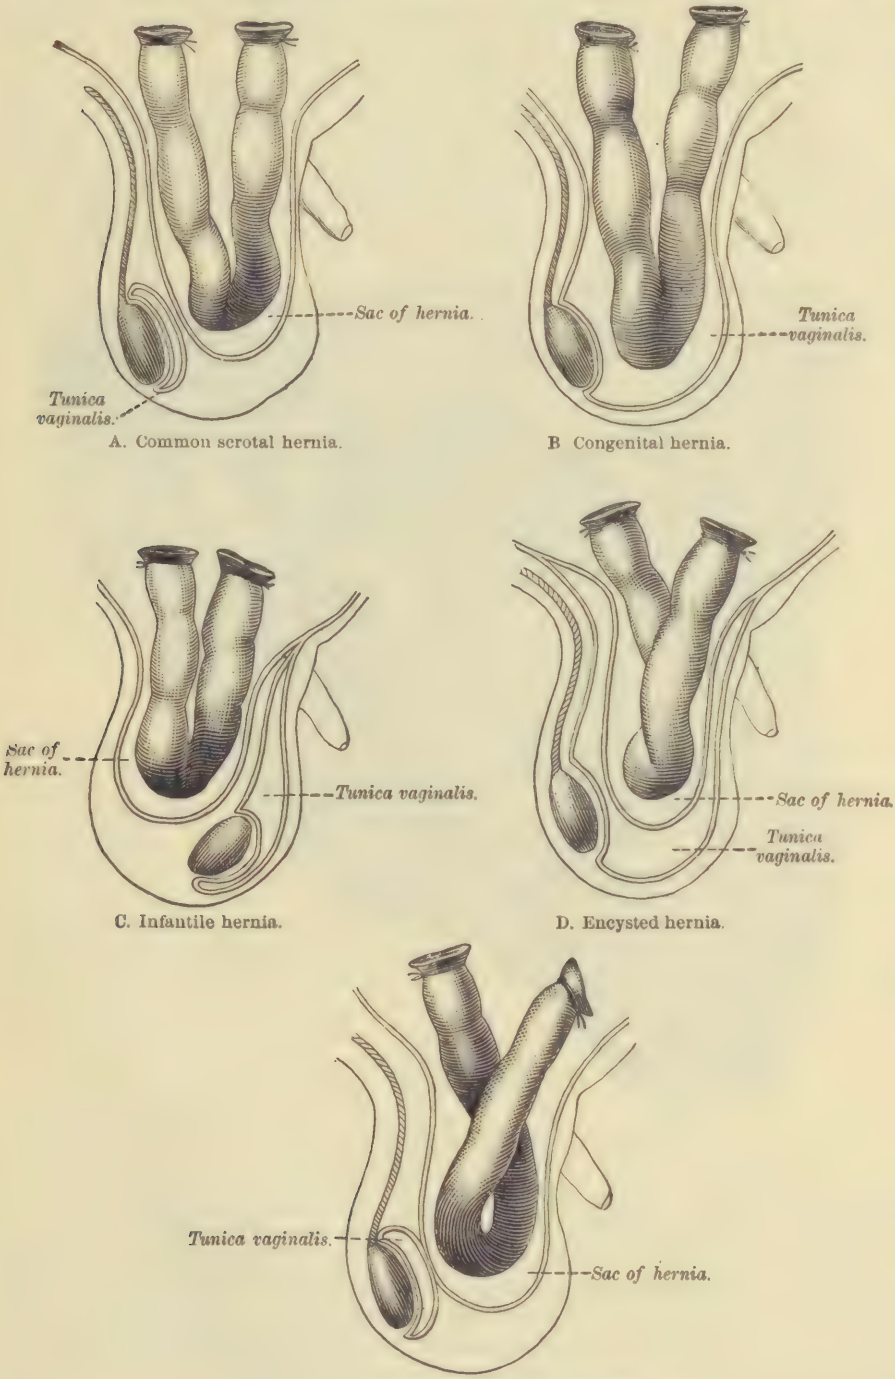
aponeurosis of the External oblique so as to lay open the inguinal canal. In dividing the stricture the direction of the incision should be upward.

When the hernia passes along the inguinal canal and escapes from the external ring into the scrotum, the condition is called **complete oblique inguinal** or **scrotal hernia** (Fig. 1120, *A*). If the hernia does not escape from the external ring, but is retained in the inguinal canal, the condition is called **incomplete inguinal hernia** or **bubonocele**. In each of these cases the coverings which invest the intestine or omentum will depend upon the extent to which it descends in the inguinal canal.

There are some other varieties of oblique inguinal hernia depending upon congenital defects in the processus vaginalis. The testicle in its descent from the abdomen into the scrotum is preceded by a pouch of peritoneum, which about

the period of birth becomes shut off from the general peritoneal cavity by a closure of that portion of the pouch which extends from the internal abdominal ring to



A. Common scrotal hernia. B Congenital hernia.

C. Infantile hernia. D. Encysted hernia.

E Hernia into the funicular process

FIG. 1120.—Varieties of oblique inguinal hernia

near the upper part of the testicle, the lower portion of the pouch remaining persistent as the tunica vaginalis. It would appear that this closure commences at

two points—viz., at the internal abdominal ring and at the top of the epididymis—and gradually extends until, in the normal condition, the whole of the intervening portion is converted into a fibrous cord. From failure in the completion of this process variations in the relation of the hernial protrusion to the testicle and tunica vaginalis are produced, which constitute distinct varieties of inguinal hernia, and which have received separate names and are of surgical importance. These are **congenital, infantile, encysted,** and **hernia of the funicular process.**

Congenital Hernia (Fig. 1120, *B*).—Where the congenital pouch of peritoneum which precedes the cord and testis in its descent remains patent throughout and is unclosed at any point, the cavity of the tunica vaginalis communicates directly with the cavity of the peritoneum. The intestine descends along this pouch into the cavity of the tunica vaginalis, which constitutes the sac of the hernia, and the gut lies in contact with the testicle.

Infantile and Encysted Hernia.—Where the congenital pouch of peritoneum is occluded at the internal ring only, but remains patent throughout the rest of its extent, two varieties of oblique inguinal hernia may be produced, which have received the names of infantile and encysted hernia. In the **infantile form** (Fig. 1120, *C*) the septum which closed the congenital sac above and the peritoneum in its immediate neighborhood yields and forms a sac, which descends behind the tunica vaginalis, so that in front of the bowel there are three layers of peritoneum, the two layers of the tunica vaginalis and the layer of the proper hernial sac. In the **encysted form** (Fig. 1120, *D*) yielding occurs in the same position as in the infantile form—namely, at the occluded spot in the pouch—and a sac forms which projects *into* and not *behind* the tunica vaginalis, as in the infantile form, and thus it constitutes a sac within a sac, so that in front of the bowel there are two layers of peritoneum—one layer of the tunica vaginalis and one of true hernial sac.

Hernia into the Funicular Process (Fig. 1120, *E*).—Where the congenital pouch of peritoneum is occluded at the lower point only—that is, just above the testicle—the intestine descends into the pouch of peritoneum as far as the testicle, but is prevented from entering the sac of the tunica vaginalis by the septum which has formed between it and the pouch, so that it resembles the congenital form in all respects, except that, instead of enveloping the testicle, that body can be felt below the rupture.

Direct Inguinal Hernia.

In direct inguinal hernia the protrusion makes its way through some part of the abdominal wall internal to the epigastric artery.

At the lower part of the abdominal wall is a triangular space, **Hesselbach's triangle**, bounded externally by the deep epigastric artery, internally by the margin of the Rectus muscle, below by Poupart's ligament (Fig. 1118). The conjoined tendon is stretched across the inner two-thirds of this space, the remaining portion of the space having only the subperitoneal areolar tissue and the transversalis fascia between the peritoneum and the aponeurosis of the External oblique muscle.

In some cases the hernial protrusion escapes from the abdomen on the outer side of the conjoined tendon, pushing before it the peritoneum, the subserous areolar tissue, and the transversalis fascia. It then enters the inguinal canal, passing along nearly its whole length, and finally emerges from the external ring, receiving an investment from the intercolumnar fascia. The coverings of this form of hernia are precisely similar to those investing the oblique form, with the insignificant difference that the infundibuliform fascia is replaced by a portion derived from the general layer of the transversalis fascia.

In other cases—and this is the more frequent variety—the hernia is either forced through the fibres of the conjoined tendon or the tendon is gradually distended in

front of it so as to form a complete investment for it. The intestine then enters the lower end of the inguinal canal, escapes at the external ring lying on the inner side of the cord, and receives additional coverings from the superficial fascia and the integument. This form of hernia has the same coverings as the oblique variety, excepting that the conjoined tendon is substituted for the Cremaster, and the infundibuliform fascia is replaced by a portion derived from the general layer of the transversalis fascia.

The difference between the position of the neck of the sac in these two forms of direct inguinal hernia has been referred, with some probability, to a difference in the relative positions of the obliterated hypogastric artery and the deep epigastric artery. When the course of the obliterated hypogastric artery corresponds pretty nearly with that of the deep epigastric the projection of these arteries toward the cavity of the abdomen produces two fossae in the peritoneum. The bottom of the external fossa of the peritoneum corresponds to the position of the internal abdominal ring, and a hernia which distends and pushes out the peritoneum lining this fossa is an oblique hernia. When, on the other hand, the obliterated hypogastric artery lies considerably to the inner side of the deep epigastric artery, corresponding to the outer margin of the conjoined tendon, it divides the triangle of Hesselbach into two parts, so that three depressions will be seen on the inner surface of the lower part of the abdominal wall—viz., an external one on the outer side of the deep epigastric artery; a middle one, between the deep epigastric and the obliterated hypogastric arteries; and an internal one, on the inner side of the obliterated hypogastric artery (pp. 1519 and 1520). In such a case a hernia may distend and push out the peritoneum forming the bottom of either fossa. These fossae are the **inguinal fossae.** When the hernia distends and pushes out the peritoneum forming the bottom of the external fossa, it is an oblique or external inguinal hernia.

When the hernia distends and pushes out the peritoneum forming the bottom of either the middle or the internal fossa, it is a direct or internal hernia.

The anatomical difference between these two forms of direct or internal inguinal hernia is that, when the hernia protrudes through the middle fossa—that is, the fossa between the deep epigastric and the obliterated hypogastric arteries—it will enter the upper part of the inguinal canal; consequently its coverings will be the same as those of an oblique hernia, with the insignificant difference that the infundibuliform fascia is replaced by a portion derived from the general layer of the transversalis fascia, whereas when the hernia protrudes through the internal fossa it is either forced through the fibres of the conjoined tendon or the tendon is gradually distended in front of it so as to form a complete investment for it. The intestine then enters the lower part of the inguinal canal, and escapes from the external abdominal ring lying on the inner side of the cord.

This form of hernia has the same coverings as the oblique variety, excepting that the conjoined tendon is substituted for the Cremaster, and the infundibuliform fascia is replaced by a portion derived from the general layer of the fascia transversalis.

The **seat of stricture** in **strangulation** in both varieties of direct hernia is most frequently at the neck of the sac or at the external ring. In that form of hernia which perforates the conjoined tendon it not unfrequently occurs at the edges of the fissure through which the gut passes. In dividing the stricture the incision should in all cases be directed upward.[1]

If the hernial protrusion passes into the inguinal canal, but does not escape

[1] In all cases of inguinal hernia, whether oblique or direct, it is proper to divide the stricture directly upward: the reason of this is obvious, for by cutting in this direction the incision is made parallel to the deep epigastric artery—either external to it in the oblique variety, or internal to it in the direct form of hernia—and thus all chance of wounding the vessel is avoided. If the incision was made outward, the artery might be divided if the hernia was direct; and if made inward, the vessel would stand an equal chance of injury if the case was one of oblique inguinal hernia.—Ed. of 15th English edition.

from the external abdominal ring, it forms what is called **incomplete direct hernia.** This form of hernia is usually of small size, and in corpulent persons is very difficult of detection.

Direct inguinal hernia is of much less frequent occurrence than the oblique, their comparative frequency being, according to Cloquet, as one to five. It occurs far more frequently in men than in women, on account of the larger size of the external ring in the former sex. It differs from the oblique in its smaller size and globular form, dependent most probably on the resistance offered to its progress by the transversalis fascia and conjoined tendon. It differs also in its position, being placed over the os pubis and not in the course of the inguinal canal. The deep epigastric artery runs on the outer or iliac side of the neck of the sac, and the spermatic cord along its external and posterior side, not directly behind it, as in oblique inguinal hernia.

FEMORAL HERNIA.

The dissection of the parts comprised in the anatomy of femoral hernia should be performed, if possible, upon a female subject free from fat. The subject should lie upon the back; a block is first placed under the pelvis, the thigh everted, and the knees slightly bent and retained in this position. An incision should then be made from the anterior superior spinous process of the ilium along Poupart's ligament to the symphysis pubis; a second incision should be carried transversely across the thigh about six inches beneath the preceding; and these are to be connected together by a vertical one carried along the inner side of the thigh (Fig. 340). These several incisions should divide merely the integument; this is to be reflected outward, when the superficial fascia will be exposed.

The **Superficial Fascia** forms a continuous layer over the whole of the thigh, consisting of areolar tissue, containing in its meshes much fat, and capable of being separated into two or more layers, between which are found the superficial vessels and nerves. It varies in thickness in different parts of the limb. In the groin it is thick, and the two layers are separated from one another by the superficial inguinal lymphatic glands, the internal saphenous vein, and several smaller vessels. One of these layers, the superficial, is continuous with the superficial fascia of the abdomen.

The superficial layer should be detached by dividing it across in the same direction as the external incisions; its removal will be facilitated by commencing at the lower and inner angle of the space, detaching it at first from the front of the internal saphenous vein, and dissecting it off from the anterior surface of that vessel and its tributaries; it should then be reflected outward in the same manner as the integument. The cutaneous vessels and nerves and superficial inguinal glands are then exposed, lying upon the deep layer of the superficial fascia. These are the internal saphenous vein and the superficial epigastric, superficial circumflex iliac, and superficial external pudic vessels, as well as numerous lymphatics, ascending with the saphenous vein to the inguinal glands.

The **internal** or **long saphenous vein** (Figs. 1121, 1122, and 1123) ascends along the inner side of the thigh, and, passing through the saphenous opening in the fascia lata, terminates in the femoral vein about an inch and a half below Poupart's ligament (Fig. 1113). This vein receives at the saphenous opening the superficial epigastric, the superficial circumflex iliac, and the superficial external pudic veins.

The **superficial external pudic artery** (superior) *arises* from the inner side of the femoral artery, and, after passing through the saphenous opening, courses inward across the spermatic cord, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male and the labium in the female, anastomosing with branches of the internal pudic.

The **superficial epigastric artery** *arises* from the femoral about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on to the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches

to the superficial inguinal lymphatic glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric and internal mammary arteries.

The **superficial circumflex iliac artery**, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the superficial inguinal lymphatic glands, the superficial fascia, and the integument of the groin, anastomosing with the deep circumflex iliac, and with the gluteal and external circumflex arteries.

The Superficial Veins (Fig. 1121).—The veins accompanying these superficial arteries are usually much larger than the arteries; they terminate in the internal or long saphenous vein at the saphenous opening.

The **superficial inguinal lymphatic glands.**—See p. 793.

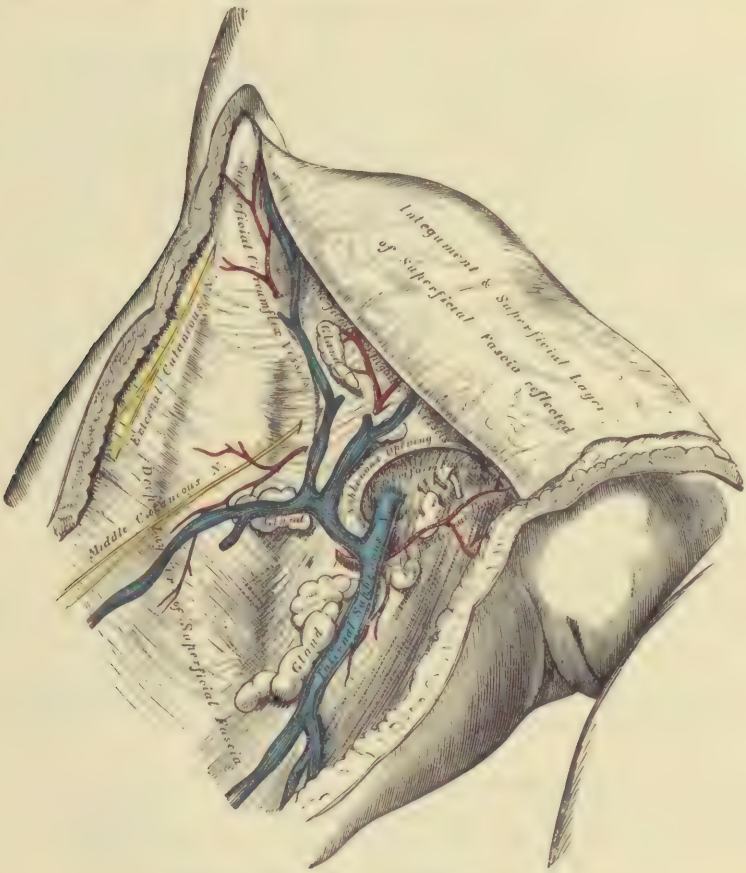


FIG. 1121.—Femoral hernia. Superficial dissection.

The **ilio-inguinal nerve** arises from the first lumbar nerve. It escapes at the external abdominal ring, and is distributed to the integument of the upper and inner part of the thigh—to the scrotum in the male and to the labium in the female. The size of this nerve is in inverse proportion to that of the ilio-hypogastric nerve. Occasionally it is very small, and ends by joining the ilio-hypogastric; in such cases a branch of the ilio-hypogastric takes the place of the ilio-inguinal, or the latter nerve may be altogether absent. The **crural branch of the genito-crural nerve** passes along the inner margin of the Psoas muscle, beneath Poupart's ligament, into the thigh, entering the sheath of the femoral vessels, and lying

superficial and a little external to the femoral artery. It pierces the anterior layer of the sheath of the vessels, and, becoming superficial by passing through the fascia lata, it supplies the skin of the anterior aspect of the thigh as far as midway between the pelvis and knee. On the front of the thigh it communicates with the outer branch of the middle cutaneous nerve, derived from the anterior crural.

The **Deep Layer of the Superficial Fascia** is a very thin fibrous layer, best marked on the inner side of the long saphenous vein and below Poupart's ligament. It is placed beneath the subcutaneous vessels and nerves, and upon the surface of the fascia lata, to which it is intimately adherent at the lower margin of Poupart's ligament. It covers the saphenous opening in the fascia lata, is closely united to its circumference, and is connected to the sheath of the femoral vessels corre-

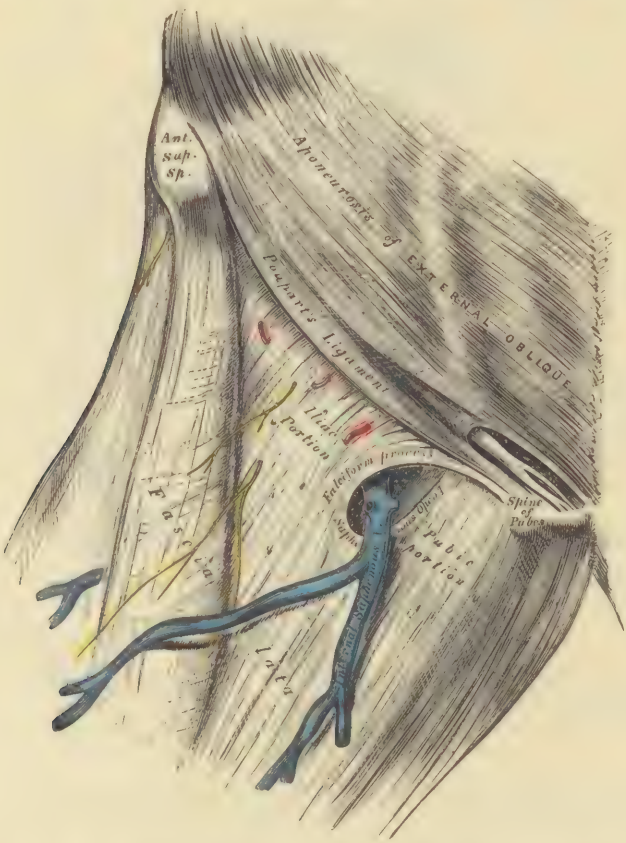

FIG. 1122.—Femoral hernia, showing fascia lata and saphenous opening.

sponding to its under surface. The portion of fascia covering this aperture is perforated by the internal saphenous vein and by numerous blood- and lymphatic vessels; hence it has been termed the **cribriform fascia**, the openings for these vessels having been likened to the holes in a sieve. The cribriform fascia adheres closely both to the superficial fascia and to the fascia lata, so that it is described by some anatomists as a part of the fascia lata, but it is usually considered (as in this work) as belonging to the superficial fascia. It is not till the cribriform fascia has been cleared away that the saphenous opening is seen, so that this opening does not in ordinary cases exist naturally, but is the result of dissection (p. 513). A femoral hernia in passing through the saphenous opening receives the cribriform fascia as one of its coverings.

The deep layer of superficial fascia, together with the cribriform fascia, having been removed, the fascia lata is exposed.

The **Fascia Lata** has been already described with the muscles of the front of the thigh (p. 513). At the upper and inner part of the thigh, a little below Poupart's ligament, a large oval-shaped aperture is observed after the superficial fascia has been cleared away; it transmits the internal saphenous vein and other smaller vessels, and is called the **saphenous opening** (Fig. 1113). In order the more correctly to consider the mode of formation of this aperture, the fascia lata in this part of the thigh is described as consisting of two portions, an **iliac portion** and a **pubic portion.**

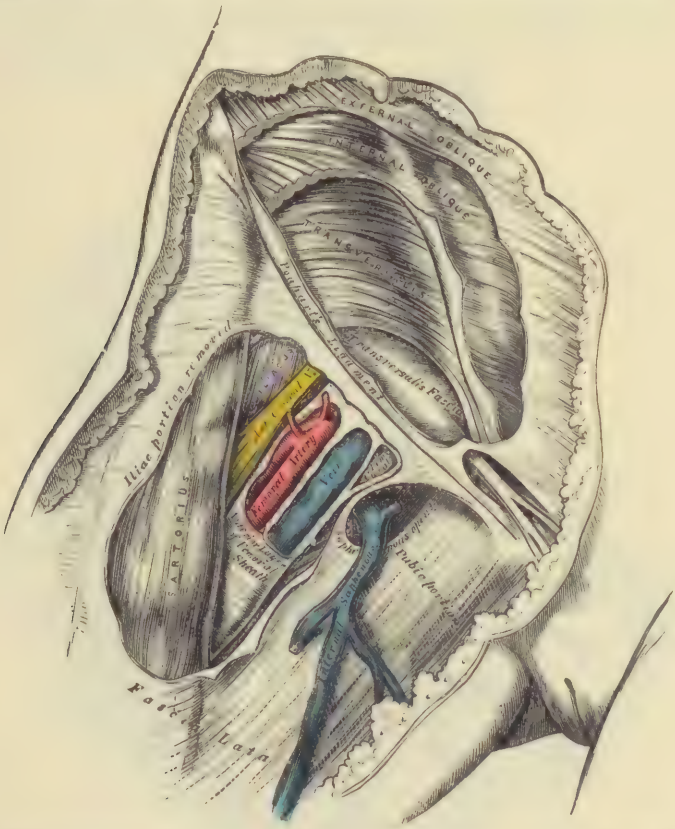

Fig. 1123.—Femoral hernia. Iliac portion of fascia lata removed, and sheath of femoral vessels and femoral canal exposed.

The **iliac portion** (Fig. 1122) is all that part of the fascia lata on the outer side of the saphenous opening. It is attached externally to the crest of the ilium and its anterior superior spine; to the whole length of Poupart's ligament; and to the pectineal line in conjunction with Gimbernat's ligament. From the spine of the os pubis it is reflected downward and outward, forming an arched margin, the **outer boundary** or **falciform process** or **superior cornu** (*cornu superius*) (Fig. 1122) of the saphenous opening. This margin overlies and is adherent to the anterior layer of the sheath of the femoral vessels; to its edge is attached the cribriform fascia, and below it is continuous with the pubic portion of the fascia lata.

The **pubic portion of the fascia lata** or the **pectineal fascia** (Fig. 1122) is situated at the inner side of the saphenous opening; at the lower margin of this aperture it is continuous with the iliac portion; traced upward, it covers the surface of the Pectineus, Adductor longus, and Gracilis muscles; and, passing behind the

sheath of the femoral vessels, to which it is loosely united, is continuous with the sheath of the Psoas and Iliacus muscles, and is attached above to the ilio-pectineal line, where it becomes continuous with the fascia covering the Iliacus muscle. From the description it may be observed that the iliac portion of the fascia lata passes in front of the femoral vessels and the pubic portion behind them, so that an apparent aperture consequently exists between the two, through which the internal saphenous vein joins the femoral vein.

The **Saphenous Opening** (*fossa ovalis*) (Figs. 1113, 1121, 1122, and 1123) is an oval-shaped aperture measuring about an inch and a half in length and half an inch in width. It is situated at the upper and inner parts of the front of the thigh, below Poupart's ligament, and is directed obliquely downward and outward. It is covered by the **cribriform fascia** (*fascia cribrosa*), a portion of the deep layer of the superficial fascia of the thigh, and which extends from the falciform margin to the pubic portion of the fascia lata or the pectineal fascia.

The **outer margin** of the saphenous opening is of a semilunar form, thin, strong, sharply defined, and lies on a plane considerably anterior to the inner margin. If this edge is traced upward, it will be seen to form a curved elongated process, the **falciform process** or **superior cornu** (Fig. 1122), which ascends in front of the femoral vessels, and, curving inward, is attached to Poupart's ligament and to the spine of the os pubis and pectineal line, where it is continuous with the pubic portion. If traced downward, it is found continuous with another curved margin, the concavity of which is directed upward and inward; this is the inferior cornu of the saphenous opening, and is blended with the pubic portion of the fascia lata covering the Pectineus muscle.

The **inner boundary of the opening** (Figs. 1113 and 1122) is on a plane posterior to the outer margin and behind the level of the femoral vessels; it is much less prominent and defined than the outer, from being stretched over the subjacent Pectineus muscle. It is through the saphenous opening that a femoral hernia passes after descending along the crural canal.

If the finger is introduced into the saphenous opening while the limb is moved in different directions, the aperture will be found to be greatly constricted on extending the limb or rotating it outward, and to be relaxed on flexing the limb and inverting it; hence the necessity for placing the limb in the latter position in employing the taxis for the reduction of a femoral hernia.

The iliac portion of the fascia lata, but not its falciform process, should now be removed by detaching it from the lower margin of Poupart's ligament, carefully dissecting it from the subjacent structures, and turning it inward, when the sheath of the femoral vessels is exposed, descending beneath Poupart's ligament (Fig. 1123).

Poupart's Ligament (*ligamentum inguinale* [*Pouparti*]) (Figs. 289, 1113, 1116, 1117, 1119, 1122, 1123, 1124, and 1125) is the lower border of the aponeurosis of the External oblique muscle, which extends from the anterior superior spine of the ilium to the spine of the os pubis. From this latter point it is reflected outward, to be attached to the pectineal line for about half an inch, forming **Gimbernat's ligament**. Its general direction is curved downward toward the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction. Its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord. Nearly the whole of the space included between Poupart's ligament and the innominate bone is filled in by the parts which descend from the abdomen into the thigh (Figs. 297, 340, and 1124). The outer half of the space (*lacuna musculorum*) is occupied by the Iliacus and Psoas muscles, together with the external cutaneous and anterior crural nerves. The pubic half of the space (*lacuna vasorum*) is occupied by the femoral vessels included in their sheath, a small oval-shaped interval existing between the femoral vein and the inner wall of the sheath,

which is occupied merely by a little loose areolar tissue, a few lymphatic vessels, and occasionally by a small lymphatic gland; this is the femoral ring, through which the gut descends in femoral hernia. The part of Poupart's ligament in front of the femoral or crural ring is called the **superficial crural arch.**

Gimbernat's Ligament (*ligamentum lacunare* [*Gimbernati*]) (Figs. 297, 340, 1113, 1124, and 1125) is that part of the aponeurosis of the External oblique muscle which is reflected backward and outward from the spine of the os pubis, to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form, with the base directed outward. Its **base** or **outer margin** is concave, thin, and sharp, and lies in contact with the femoral sheath. Its **apex** corresponds to the spine of the os pubis. Its **posterior margin** is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its **anterior margin** is continuous with Poupart's ligament.

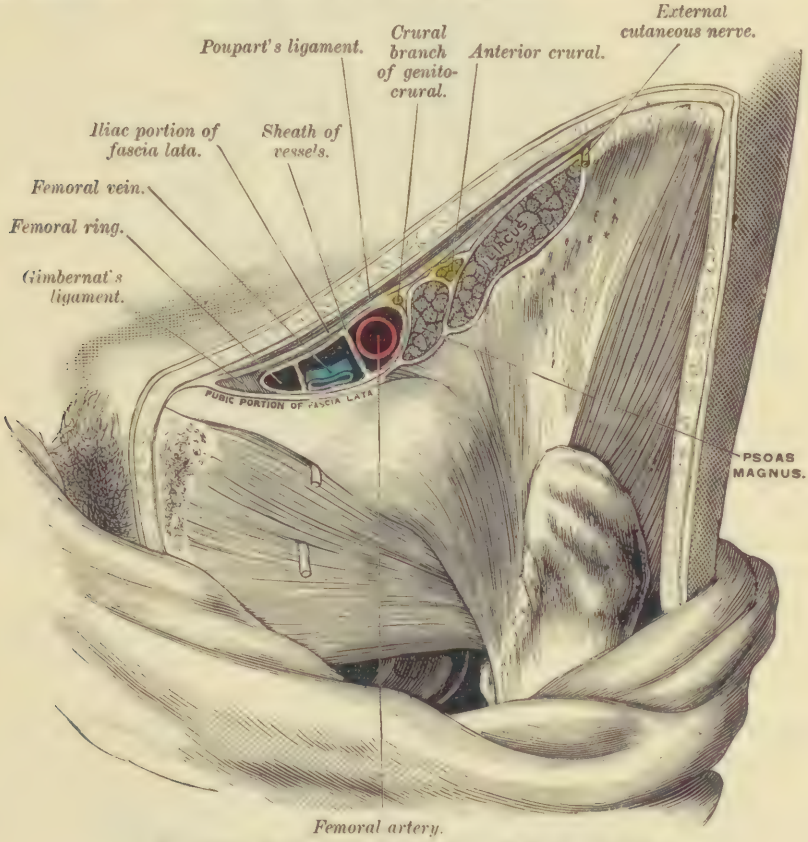

FIG. 1124.—Structures which pass beneath the crural arch.

Femoral Sheath (Fig. 1124). —The femoral or **crural sheath** is a continuation downward of the fasciae that line the abdomen, the **transversalis fascia** passing down in front of the femoral vessels, and the **iliac fascia** descending behind them; these fasciae are directly continuous on the iliac side of the femoral artery, but a small space exists between the femoral vein and the point where they are continuous on the pubic side of that vessel, which constitutes the **femoral** or **crural canal** (Fig. 1113). The femoral sheath is closely adherent to the contained vessels about an inch below the saphenous opening, being blended with the areolar sheath of the vessels, but opposite Poupart's ligament it is much larger than is required to contain them; hence the funnel-shaped form which it presents. The outer border of the sheath

is perforated by the genito-crural nerve. Its inner border is pierced by the internal saphenous vein and numerous lymphatic vessels. In front it is covered by the iliac portion of the fascia lata; and behind it is the pubic portion of the same fascia.

If the anterior wall of the sheath is removed (Fig. 1113), the femoral artery and vein are seen lying side by side, a thin septum separating the two vessels, while another septum may be seen lying just internal to the vein, and cutting off a small space between the vein and the inner wall of the sheath. The septa are stretched between the anterior and posterior walls of the sheath, so that each vessel is enclosed in a separate compartment. The interval left between the vein and the inner wall of the sheath is not filled up by any structure, excepting a little loose areolar tissue, a few lymphatic vessels, and occasionally by a small lymphatic gland; this is the **femoral** or **crural canal** (Fig. 1113), through which the intestine descends in femoral hernia.

Deep Crural Arch.—Passing across the front of the femoral sheath on the abdominal side of Poupart's ligament, and closely connected with it, is a thickened band of fibres of the transversalis fascia, called the **deep crural arch**. It is apparently a thickening of the transversalis fascia, joining externally to the centre of Poupart's ligament, and arching across the front of the crural sheath, to be inserted by a broad attachment into the pectineal line behind the conjoined tendon. In some subjects this structure is not very prominently marked, and not infrequently it is altogether wanting. The **superficial crural arch** is the portion of Poupart's ligament in front of the femoral ring.

The **Femoral** or **Crural Canal** (*canalis femoralis*) (Figs. 297, 340, and 1113) is the narrow interval between the femoral vein and the inner wall of the femoral sheath. It exists as a distinct canal only when the sheath has been separated from the vein by dissection or by the pressure of a hernia or tumor. Its length is from a quarter to half an inch, and it extends from the femoral ring to the upper part of the saphenous opening.

Its **anterior wall** is very narrow, and formed by a continuation downward of the transversalis fascia, under Poupart's ligament, covered by the falciform process of the fascia lata.

Its **posterior wall** is formed by a continuation downward of the iliac fascia covering the pubic portion of the fascia lata.

Its **outer wall** is formed by the fibrous septum separating it from the inner side of the femoral vein.

Its **inner wall** is formed by the junction of the processes of the transversalis and iliac fasciae, which form the inner side of the femoral sheath, and lies in contact at its commencement with the outer edge of Gimbernat's ligament.

This canal has two orifices—an upper one, the **femoral** or **crural ring**, closed by the septum crurale; and a lower one, the **saphenous opening**, closed by the cribriform fascia.

The **femoral** or **crural ring** (*annulus femoralis*) (Figs. 1113, 1124, and 1125) is the upper opening of the femoral canal, and leads into the cavity of the abdomen. It is bounded in front by Poupart's ligament and the deep crural arch; behind, by the os pubis, covered by the Pectineus muscle and the pubic portion of the fascia lata; internally, by the base of Gimbernat's ligament, the conjoined tendon, the transversalis fascia, and the deep crural arch; externally, by the fibrous septum lying on the inner side of the femoral vein. The femoral ring is of an oval form; its long diameter, directed transversely, measures about half an inch, and it is larger in the female than in the male, which is one of the reasons of the greater frequency of femoral hernia in the former sex.

Position of Parts around the Ring.—The spermatic cord in the male and round ligament in the female lie immediately above the anterior margin of the

femoral ring, and may be divided in an operation for femoral hernia if the incision for the relief of the stricture is not of limited extent. In the female this is of little importance, but in the male the spermatic artery and vas deferens may be divided.

The **femoral vein** lies on the outer side of the ring.

The **deep epigastric artery** in its passage upward and inward from the external iliac artery passes across the upper and outer angle of the crural ring, and is consequently in danger of being wounded if the stricture is divided in a direction upward and outward.

The **communicating branch** between the deep epigastric and obturator lies in front of the ring.

The circumference of the ring is thus seen to be bounded by vessels in every part, excepting internally and behind (Fig. 1125). It is in the former position that the stricture is divided in cases of strangulated femoral hernia.

The **obturator artery** (p. 688), when it arises by a common trunk with the deep epigastric (p. 689), which occurs once in every three subjects and a half, bears a very important relation to the crural ring. In most cases it descends on the

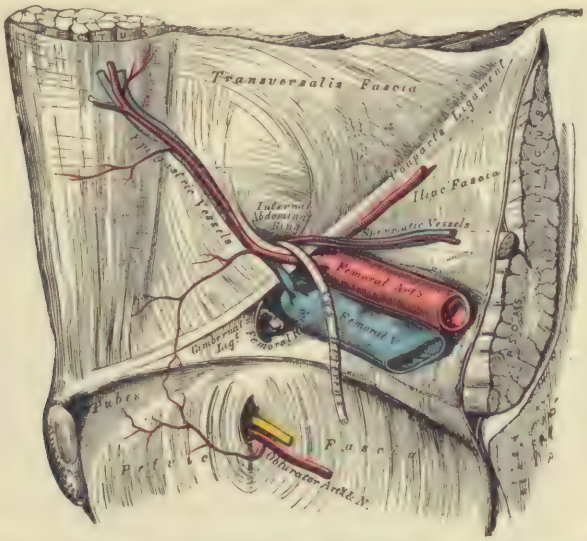

FIG. 1125.—Hernia. The relations of the femoral and internal abdominal rings, seen from within the abdomen. Right side.

inner side of the external iliac vein to the obturator foramen, and will consequently lie on the outer side of the crural ring, where there is no danger of its being wounded in the operation for dividing the stricture in femoral hernia (Fig. 427 *A*, p. 689). Occasionally, however, the obturator artery curves along the free margin of Gimbernat's ligament in its passage to the obturator foramen; it would consequently skirt along the greater part of the circumference of the crural ring, and could hardly avoid being wounded in the operation (Fig. 427 *B*, p. 689).

The Crural Septum or Septum Crurale (*septum femorale musculus*) (Fig. 297).—The femoral ring is closed by a thin process of transversalis fascia containing fat and called, by J. Cloquet, the **septum crurale**. This serves as a barrier to the protrusion of a hernia through this part. Its upper surface is slightly concave, and supports a small lymphatic gland (Fig. 1125), by which it is separated from the subserous areolar tissue and peritoneum. Its under surface is turned toward the femoral canal. The septum crurale is perforated by numerous apertures for the passage of lymphatic vessels connecting the deep inguinal lymphatic glands with those surrounding the external iliac artery.

The size of the femoral canal, the degree of tension of its orifices, and consequently the degree of constriction of a hernia, vary according to the position of the limb. If the leg and thigh are extended, abducted, or everted, the femoral canal and its orifices are rendered tense from the traction on these parts by Poupart's ligament and the fascia lata, as may be ascertained by passing the finger along the canal. If, on the contrary, the thigh is flexed upon the pelvis, and at the same time adducted and rotated inward, the femoral canal and its orifices become considerably relaxed; for this reason the limb should always be placed in the latter position when the application of the taxis is made in attempting the reduction of a femoral hernia.

The **subperitoneal areolar tissue** is continuous with the subserous areolar tissue of surrounding parts. It is usually thickest and most fibrous where the iliac vessels leave the abdominal cavity. It covers over the femoral ring, the small interval on the inner side of the femoral vein. In some subjects it contains a considerable amount of adipose tissue. In such cases, where it is protruded forward in front of the sac of a femoral hernia, it may be mistaken for a portion of omentum. The peritoneum lining the portion of the abdominal wall between Poupart's ligament and the brim of the pelvis is similar to that lining any other portion of the abdominal wall, being very thin. Here there is no natural aperture for the escape of intestine.

Descent of the Hernia.—From the preceding description it follows that the femoral ring must be a weak point in the abdominal wall; hence it is that when violent or long-continued pressure is made upon the abdominal viscera a portion of intestine may be forced into it, constituting a femoral hernia; and the changes in the tissues of the abdomen which are produced by pregnancy, together with the larger size of this aperture in the female, serve to explain the frequency of this form of hernia in women.

When a portion of the intestine passes through the femoral ring, a pouch of peritoneum lies before it, which forms what is called the **hernial sac**; it is covered by the subserous areolar tissue, receives an investment from the septum crurale, and descends vertically along the crural canal in the inner compartment of the sheath of the femoral vessels as far as the saphenous opening; at this point it changes its course, being prevented from extending farther down the sheath on account of the narrowing of the sheath and its close contact with the vessels, and also from the close attachment of the superficial fascia and crural sheath to the lower part of the circumference of the saphenous opening; the hernia is consequently directed forward, pushing before it the cribriform fascia, and then curves upward on to the falciform process of the fascia lata and lower part of the tendon of the External oblique, being covered by the superficial fascia and integument. While the hernia is contained in the femoral canal it is usually of small size, owing to the resisting nature of the surrounding parts; but when it has escaped from the saphenous opening into the loose areolar tissue of the groin, it becomes considerably enlarged. The direction taken by a femoral hernia in its descent is at first downward, then forward and upward; this should be borne in mind, as in the application of the taxis for the reduction of a femoral hernia pressure should be directed in the reverse order.

Coverings of the Complete Hernia.—The coverings of a femoral hernia, from within outward, are—peritoneum, subserous areolar tissue, the septum crurale, crural sheath, cribriform fascia, superficial fascia, and integument.[1]

[1] Sir Astley Cooper has described an investment for femoral hernia, under the name of "fascia propria," lying immediately external to the peritoneal sac, but frequently separated from it by more or less adipose tissue. Surgically, it is important to remember the existence (at any rate, the occasional existence) of this layer, on account of the ease with which an inexperienced operator may mistake the fascia for the peritoneal sac and the contained fat for omentum. Anatomically, this fascia appears identical with what is called in the text "subserous areolar tissue," the areolar tissue being thickened and caused to assume a membranous appearance by the pressure of the hernia.—Ed. of 15th English edition.

Varieties of Femoral Hernia.—If the hernia descends along the femoral canal only as far as the saphenous opening, and does not escape from this aperture, the condition is called **incomplete femoral hernia.** The small size of the protrusion in this form of hernia, which is due to the firm and resisting nature of the canal in which it is contained, renders it an exceedingly dangerous variety, from the extreme difficulty of detecting the existence of the swelling, especially in corpulent subjects. The coverings of an incomplete femoral hernia, named from without inward, are as follows: the integument, superficial fascia, iliac portion of fascia lata, crural sheath, septum crurale, subserous areolar tissue, and peritoneum. When, however, the hernia protrudes through the saphenous opening and directs itself forward and upward, it forms a **complete femoral hernia**, the coverings of which have been given (p. 1533). Occasionally the hernial sac descends on the iliac side of the femoral vessels or in front of these vessels, or even sometimes behind them.

The **seat of stricture in a strangulated femoral hernia** varies; it may be in the peritoneum at the neck of the hernial sac; in the greater number of cases it would appear to be at the point of junction of the falciform process of the fascia lata with the lunated edge of Gimbernat's ligament, or at the margin of the saphenous opening in the thigh. The stricture should in every case be divided in an inward direction, or upward and inward, and the extent of the necessary cut in the majority of cases is about two or three lines. By these means all vessels or other structures of importance in relation with the neck of the hernial sac will be avoided.

SURGICAL ANATOMY OF THE PERINÆUM.

Dissection.—The student should select a well-developed muscular subject, free from fat, and the dissection should be commenced early, in order that the parts may be examined in as recent a state as possible. A staff having been introduced into the bladder and the subject placed in the position shown in Fig. 1126, the scrotum should be raised upward, and retained in that position, and the rectum moderately distended with tow.

The **Perinæum** corresponds to the inferior aperture or outlet of the pelvis. Its deep boundaries are, in front, the pubic arch and subpubic ligament; behind, the tip of the coccyx; and on each side, the rami of the os pubis and ischium, the tuberosities of the ischium, and great sacro-sciatic ligaments. The space included by these boundaries is somewhat lozenge-shaped, and is limited on the surface of

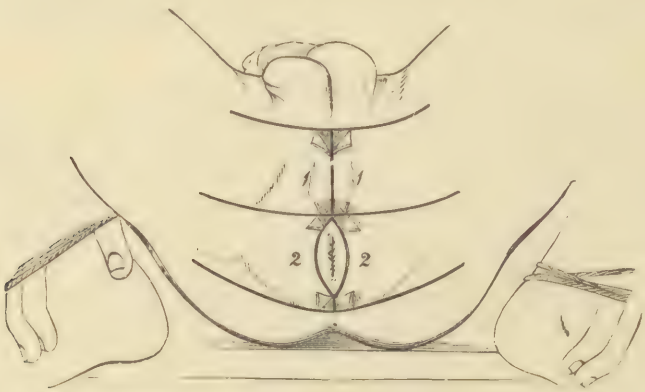

FIG. 1126.—Dissection of perinæum and ischio-rectal region.

the body by the scrotum in front, by the buttocks behind, and on each side by the inner side of the thigh. A line drawn transversely between the anterior parts of the tuberosities of the ischium, on each side, in front of the anus, divides this space into two portions. The anterior portion contains the penis and urethra, and is called the **perinæum proper** or **genito-urinary region**. The posterior portion contains the termination of the rectum, and is called the **ischio-rectal** or **anal region**.

ISCHIO-RECTAL REGION.

The ischio-rectal region contains the termination of the rectum and a deep fossa, filled with fat, on each side of the intestine, between it and the tuberosity of the ischium; this is called the ischio-rectal fossa.

The ischio-rectal region presents in the middle line the **aperture of the anus**; around this orifice the integument is thrown into numerous folds, which are obliterated on distention of the anus. The integument is of a dark color, continuous with the mucous membrane of the rectum, and is provided with numerous

follicles, which occasionally inflame and suppurate, and may be mistaken for fistulæ. The veins around the margin of the anus are occasionally much dilated, forming a number of hard pendent masses, of a dark bluish color, covered partly by mucous membrane and partly by the integument. These tumors constitute the disease called **external piles.**

Dissection (Fig. 1126).—Make an incision through the integument, along the median line, from the base of the scrotum to the anterior extremity of the anus: carry it around the margins of this aperture to its posterior extremity, and continue it backward to about an inch behind the tip of the coccyx. A transverse incision should now be carried across the base of the scrotum, joining the anterior extremity of the preceding; a second, carried in the same direction, should be made in front of the anus; and a third at the posterior extremity of the first incision. These incisions should be sufficiently extensive to enable the dissector to raise the integument from the inner side of the thighs. The flaps of skin corresponding to the ischio-rectal region should now be removed. In dissecting the integument from this region great care is required, otherwise the Corrugator cutis ani and External sphincter will be removed, as they are intimately adherent to the skin.

The **Superficial Fascia** is exposed on the removal of the skin; it is very thick, areolar in texture, and contains much fat in its meshes. In it are found ramifying two or three branches of the perforating cutaneous nerve; these turn around the inferior border of the Gluteus maximus and are distributed to the integument around the anus.

In this region, and connected with the lower end of the rectum, are four muscles: the Corrugator cutis ani; the two Sphincters, External and Internal; and the Lævator ani.

These muscles have been already described (p. 449).

The **Ischio-rectal Fossa** (*fossa ischiorectalis*) (Figs. 300 and 304) is situated between the end of the rectum and the ischial tuberosity. It is triangular in shape; its base, directed to the surface of the body, is formed by the integument of the ischio-rectal region; its **apex,** directed upward, corresponds to the point of division of the obturator fascia and the thin membrane given off from it, which covers the outer surface of the Lævator ani (ischio-rectal or anal fascia). Its dimensions are about an inch in breadth at the base and about two inches in depth, being deeper behind than in front. It is bounded, *internally*, by the Sphincter ani, Lævator ani, and Coccygeus muscles; *externally*, by the tuberosity of the ischium and the obturator fascia, which covers the inner surface of the Obturator internus muscle; *in front*, it is limited by the line of junction of the superficial fascia with the base of the triangular ligament; and *behind*, by the margin of the Gluteus maximus muscle and the great sacro-sciatic ligament. This space is filled with a large mass of adipose tissue, which explains the frequency with which abscesses in the neighborhood of the rectum burrow to a considerable depth.

If the subject has been injected, on placing the finger on the outer wall of this fossa the internal pudic artery, with its accompanying veins and the two divisions of the nerve, will be felt about an inch and a half above the margin of the ischiatic tuberosity, but approaching nearer the surface as they pass forward along the inner margin of the pubic arch. These structures are enclosed in a sheath, the **fascial canal** or **canal of Alcock** (Figs. 304 and 1131), formed by the obturator fascia, the pudic nerve lying below the artery and the dorsal nerve of the penis above it. Crossing the space transversely, about its centre are the inferior hemorrhoidal vessels and nerves, which are distributed to the integument of the anus and to the muscles of the lower end of the rectum. These vessels are occasionally of large size, and may give rise to troublesome hemorrhage when divided in the operation of lithotomy or in that for fistula in ano. At the back part of this space, near the coccyx, may be seen a branch of the fourth sacral nerve, and at the forepart of the space the superficial perineal vessels and nerves can be seen for a short distance.

THE PERINÆUM PROPER IN THE MALE.

The perineal space is of a triangular form; its deep boundaries are limited, laterally, by the rami of the pubic bones and ischia, meeting in front at the pubic arch; behind, by an imaginary transverse line extending between the anterior parts of the tuberosities of the ischia. The lateral boundaries are, in the adult, from three inches to three inches and a half in length, and the base from two to three inches and a half in breadth, the average extent of the space being two inches and three-quarters.

The variations in the diameter of this space are of extreme interest in connection with the operation of lithotomy and the extraction of a stone from the cavity of the bladder. In those cases where the tuberosities of the ischia are near together it would be necessary to make the incisions in the lateral operation of lithotomy less oblique than if the tuberosities were widely separated, and the perineal space consequently wider. The perinæum is subdivided by the median raphé into two equal parts. Of these, the left is the one in which the operation of lithotomy is performed.

In the middle line the perinæum is convex, and corresponds to the bulb of the urethra. The skin covering it is of a dark color, thin, freely movable upon the subjacent parts, and covered with sharp crisp hairs, which should be removed before the dissection of the part is commenced. In front of the anus a prominent line commences, the **raphé**, continuous in front with the raphé of the scrotum. The skin of the raphé is adherent to the deep layer of the superficial fascia.

Upon removing the skin and the superficial layer of the superficial fascia, in the manner shown in Fig. 1126, a plane of fascia will be exposed, covering in the triangular space and stretching across from one ischio-pubic ramus to the other. This is the **deep layer of the superficial fascia** or **fascia of Colles** (*fascia superficialis perinæi*). It has already been described (p. 456). It is a layer of considerable strength, and encloses and covers a space in which are contained muscles, vessels, and nerves. It is continuous in front with the fascia of the penis and the dartos of the scrotum; on each side it is firmly attached to the margin of the ischio-pubic ramus and to the tuberosity of the ischium; and posteriorly it curves down behind the Transversalis perinaei muscles to join the base of the triangular ligament.

It is between this layer of fascia and the triangular ligament of the urethra that extravasation of urine most frequently takes place in cases of rupture of the urethra. The triangular ligament of the urethra (p. 459) is attached to the ischio-pubic rami, and in front to the subpubic ligament. It is clear, therefore, that when extravasation of fluid takes place between these two layers, it cannot pass backward, because the two layers are continuous with each other around the Transversi perinaei muscles: it cannot extend laterally, on account of the connection of both these layers to the rami of the os pubis and ischium; it cannot find its way into the pelvis because the opening into this cavity is closed by the triangular ligament, and, therefore, so long as these two layers remain intact, the only direction in which the fluid can make its way is forward into the areolar tissue of the scrotum and penis, and then on to the anterior wall of the abdomen.

When the deep layer of the superficial fascia is removed (Fig. 1127), a space is exposed, between this fascia and the triangular ligament, in which are contained the superficial perineal vessels and nerves and some of the muscles connected with the penis and urethra—viz., in the middle line, the Accelerator urinae; on each side, the Erector penis; and behind, the transversus perinaei; together with the crura of the corpora cavernosa and the bulb of the corpus spongiosum. Here also is seen the **central tendinous point of the perinæum.** This is a fibrous point in the middle line of the perinæum between the urethra and the rectum, being about half an inch in front of the anus. At this point four muscles converge and are attached—viz., the External sphincter ani, the Accelerator urinae, and the two Transversi perinaei

muscles; so that by the contraction of these muscles, which extend in opposite directions, it serves as a fixed point of support.

The Accelerator urinae, the Erector penis, and the Superficial transversus perinaei muscles have been already described (p. 457). They form a triangular space (Fig. 1127), bounded, internally, by the Accelerator urinae; externally, by the Erector penis; and behind, by the Transversus perinaei. The floor of this space is formed by the triangular ligament of the urethra; and running from behind forward in it are the superficial perineal vessels and nerves, and the transverse perineal artery coursing along the posterior boundary of the space, on the Transversus perinaei muscle.

The Accelerator urinae and Erector penis should now be removed, when the triangular ligament of the urethra will be exposed, stretching across the front of the outlet of the pelvis. The urethra is seen perforating its centre, just behind the bulb; and on each side is the crus penis, connecting the corpus cavernosum with the rami of the ischium and os pubis.

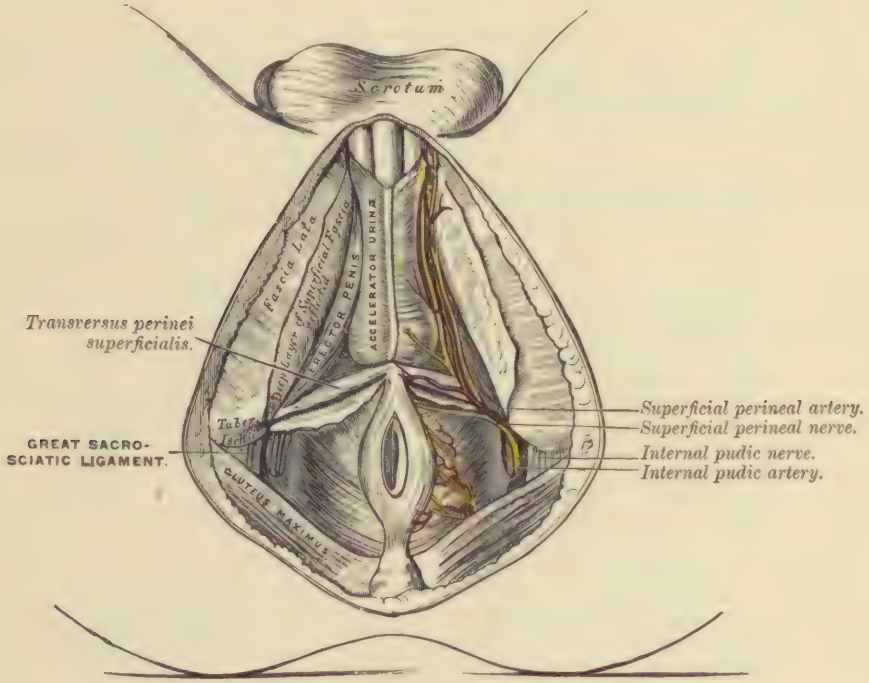

FIG. 1127.—The superficial muscles and vessels of the perinæum.

The **Triangular Ligament** or the **Deep Perineal Fascia** (*trigonum urogenitale* or *diaphragma urogenitale*) (Figs. 309, 310, and 1128), which has been already described (p. 459), consists of two layers, the **inferior anterior** or **superficial layer** (*fascia trigoni urogenitalis inferior*) of which is now exposed. It is united to the superior or deep layer behind, but is separated in front by a subfascial space in which are contained certain structures.

The **inferior layer of the triangular ligament** (Figs. 305 and 310) consists of a strong fibrous membrane, the fibres of which are disposed transversely, which stretches across from one ischio-pubic ramus to the other and completely fills in the pubic arch; it is attached in front to the subpubic ligament, except just in the centre, where a small interspace is left for the dorsal vein of the penis. In the erect position of the body it is almost horizontal. It is perforated by the urethra in the middle line, and on each side of the urethral opening by the ducts of Cowper's glands and by the arteries of the bulb; in front, and external to this, by the artery

of the corpus cavernosum, immediately before this vessel enters the crus penis. Near its apex the ligament is perforated by the termination of the pudic artery and by the dorsal nerve of the penis. The apex of the triangular ligament is known as the **transverse perineal ligament**. The **crura penis** are exposed, lying superficial to this ligament. They will be seen to be attached by blunt-pointed processes to the rami of the os pubis and ischium, in front of the tuberosities, and passing forward and inward, joining to form the body of the penis. In the middle line the bulb and corpus spongiosum are exposed by the removal of the Accelerator urinae muscle.

If the inferior layer of the triangular ligament is detached on either side, the deep perineal interspace will be exposed and the following parts will be seen between it and the deep layer of the ligament: the subpubic ligament in front, close to the symphysis pubis; the dorsal vein of the penis; the membranous portion of the urethra and the Compressor urethrae muscle; Cowper's glands and their ducts; the pudic vessels and the dorsal nerve of the penis; the artery and nerve of the bulb and a plexus of veins.

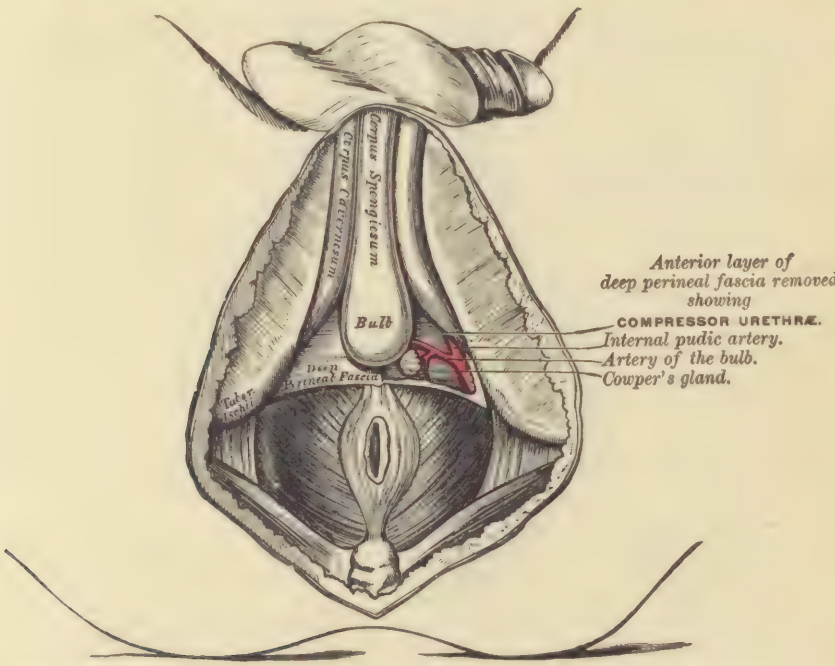

FIG. 1128.—Deep perineal fascia. On the left side the anterior layer has been removed.

The **superior, deep,** or **posterior layer of the triangular ligament** or **deep perineal fascia** (*fascia trigoni urogenitalis superior*) (Fig. 305) is derived from the obturator fascia, and is continuous with it along the pubic arch. Behind, it joins with the inferior layer of the triangular ligament, and is continuous with the **anal fascia**. Above it is the prostate gland (Fig. 1129), supported by the anterior fibres of the Levator ani, which act as a sling for the gland and form the Levator prostatae muscle. The superior layer of the triangular ligament is continuous around the anterior free edge of this muscle with the layer of recto-vesical fascia covering the prostate gland. The superior layer of the triangular ligament is perforated by the urethra. Between the two layers of the triangular ligament are situated the membranous part of the urethra, enveloped by the Compressor urethrae muscle (Fig. 309); the ducts of Cowper's glands; the arteries to the bulb; the pudic vessels and the dorsal nerve of the penis. The membranous part of the urethra is about three-quarters of an inch in length, and passes downward and

forward behind the symphysis pubis, from which it is distant about an inch. It is the narrowest part of the tube, and is enveloped, as has already been stated, by the Compressor urethrae muscle.

The **Compressor urethrae** has already been described (p. 460). In addition to this muscle, and immediately beneath it, **circular muscular fibres** surround the membranous portion of the urethra from the bulb in front to the prostate behind, and are continuous with the muscular fibres of the bladder. These fibres are involuntary.

Cowper's glands (Figs. 303, 1128, and 1129) are situated immediately below the membranous portion of the urethra, close behind the bulb, and below the artery of the bulb.

The **Pudic Vessels** (Figs. 1128 and 1129) and **Dorsal Nerve of the Penis** (Fig. 310) are placed along the inner margin of the pubic arch (p. 1536).

The **Artery of the Bulb** (Figs. 1128 and 1129, and p. 691) passes transversely inward, from the internal pudic artery (p. 689) along the base of the triangular

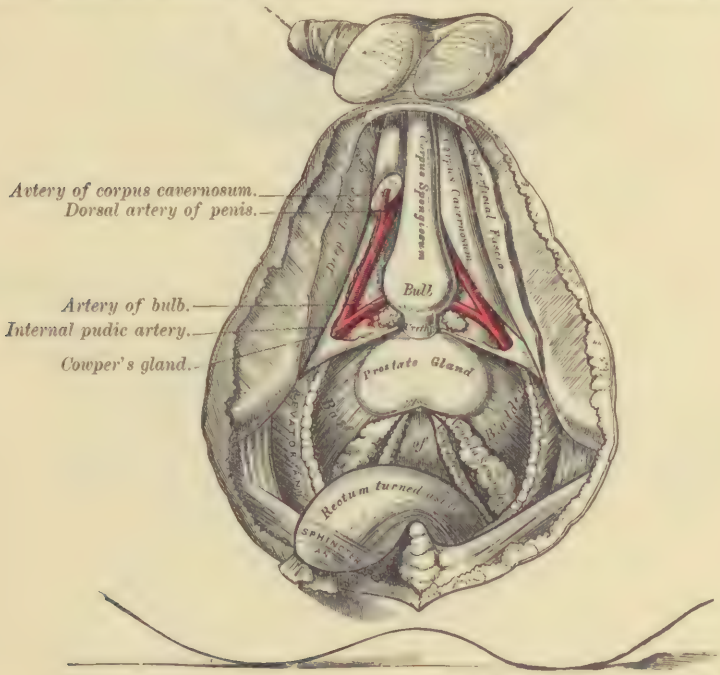

FIG. 1129.—A view of the position of the viscera at the outlet of the pelvis.

ligament, between its two layers, accompanied by a branch of the pudic nerve. If the superior layer of the triangular ligament is removed and the crus penis of one side detached from the bone, the under or perineal surface of the Levator ani muscle, covered by the anal fascia, is brought fully into view (Figs. 302, 303, and 304). This muscle, with the triangular ligament in front and the Coccygeus and Pyriformis behind, closes the outlet of the pelvis.

The Levator ani and Coccygeus muscles have already been described (p. 451).

Position of the Viscera at the Outlet of the Pelvis.—Divide the central tendinous point of the perinæum, separate the rectum from its connections by dividing the fibres of the Levator ani, which descend upon the sides of the prostate gland, and draw the gut backward toward the coccyx, when the under surface of the prostate gland, the neck and base of the bladder, the vesiculæ seminales, and the vasa deferentia will be exposed.

The **Prostate Gland** (p. 1129) is a pale, firm, glandular body which is placed immediately below the neck of the bladder, around the commencement of the

urethra. It is placed in the pelvic cavity, behind the lower part of the symphysis pubis, above the superior layer of the triangular ligament, and rests upon the rectum, through which it may be distinctly felt, especially when enlarged. In shape and size it resembles a chestnut. Its base is directed upward toward the neck of the bladder. Its apex is directed downward to the deeper layer of the triangular ligament, which it touches.

Its posterior surface is smooth, marked by a slight longitudinal furrow, and rests on the second part of the rectum, to which it is connected by areolar tissue. Its anterior surface is flattened, marked by a slight longitudinal furrow, and placed about three-quarters of an inch below the pubic symphysis. It measures about an inch and a half in its transverse diameter at the base, an inch in its antero-posterior diameter, and three-quarters of an inch in depth. Hence the greatest extent of incision that can be made in it without dividing its substance completely across is obliquely backward and outward. This is the direction in which the incision is made in it in the lateral operation of lithotomy. The prostate has a sheath derived from the recto-vesical fascia (p. 1449).

Above the prostate a small triangular portion of the bladder is seen (Fig. 1129), bounded, in front and below, by the prostate gland; above, by the recto-vesical fold of the peritoneum; on each side, by the seminal vesicle and the vas deferens. It is separated from direct contact with the rectum by the recto-vesical fascia. The relation of this portion of the bladder to the rectum is of extreme interest to the surgeon. In cases of retention of urine this portion of the organ is found projecting into the rectum, between three and four inches from the margin of the anus, and may be easily perforated without injury to any important parts. This portion of the bladder was consequently selected in the old days for the performance of the now obsolete operation of tapping the bladder.

Surgical Anatomy. Median Lithotomy.—As the incision is in the raphé, the hemorrhage is trivial, and there is but slight risk of injuring the pelvic fascia. But the operation gives little room for manipulation and is inadmissible in children, because in them dilatation of the wound may tear the bladder loose from the urethra. A risk of median lithotomy is division of the artery of the bulb.

In median lithotomy a grooved staff is introduced, the groove being median. The knife is introduced in the mid-line, just in front of the anal margin, and hits the staff near the apex of the prostate; the entire length of the membranous urethra is cut as the instrument is withdrawn.

Parts Divided.—Skin, superficial fascia, sphincter ani muscle, central tendon of the perinæum, inferior leaf of the triangular ligament, membranous urethra, and the Compressor urethræ muscle.

Lateral Lithotomy.—The operation is performed on the left side of the perinæum, as this is most convenient for the right hand of the operator. A grooved staff having been introduced into the bladder, the first incision is commenced midway between the anus and the back of the scrotum (*i. e.*, in an ordinary adult perinæum about an inch and a half in front of the anus) a little on the left side of the raphé, and is carried obliquely backward and outward to midway between the anus and tuberosity of the left ischium. The incision divides the integument and superficial fascia, the inferior hemorrhoidal vessels and nerves, and the superficial and transverse perineal vessels. If the forefinger of the left hand is thrust upward and forward into the wound, pressing at the same time the rectum inward and backward, the staff may be felt in the membranous portion of the urethra. The finger is fixed upon the staff, and the structures covering the staff are divided with the point of the knife, which must be directed along the groove toward the bladder, the edge of the knife being turned outward and backward, dividing in its course the membranous portion of the urethra and part of the left lobe of the prostate gland to the extent of about an inch. The knife is then withdrawn, and the forefinger of the left hand passed along the staff into the bladder. The position of the stone having been ascertained, the staff is to be withdrawn, and the forceps is introduced over the finger into the bladder. If the stone is very large, the opposite side of the prostate may need to be notched before the forceps is introduced; the finger is now withdrawn, and the blades of the forceps opened and made to grasp the stone, which must be extracted by slow and cautious undulating movements.

Parts Divided in the Operation.—The various structures divided in this operation are as follows: the integument, superficial fascia, inferior hemorrhoidal vessels and nerves, and prob-

ably the superficial perineal vessels and nerves, the posterior fibres of the Accelerator urinae muscle, the Transversus perinaei muscle and artery, the triangular ligament, the anterior fibres of the Levator ani muscle, part of the Compressor urethrae muscle, the membranous and prostatic portions of the urethra, and part of the prostate gland.

Parts to be Avoided in the Operation.—In making the necessary incisions in the perinæum for the extraction of a calculus the following parts should be avoided: The primary incision should not be made too near the middle line, for fear of wounding the bulb of the corpus spongiosum or the rectum; nor too far externally, otherwise the internal pudic artery may be implicated as it ascends along the inner border of the pubic arch. If the incisions are carried too far forward, the artery of the bulb may be divided; if carried too far backward, the entire breadth of the prostate and neck of the bladder may be cut through, which allows the urine to become infiltrated behind the pelvic fascia into the loose areolar tissue between the bladder and rectum, instead of escaping externally; diffuse inflammation is consequently set up, and peritonitis, from the close proximity of the recto-vesical peritoneal fold, is the result. If, on the contrary, only the anterior part of the prostate is divided, the urine makes its way externally, and there is less danger of infiltration taking place.

During the operation it is of great importance that the finger should be passed into the bladder *before* the staff is removed; if this is neglected, and if the incision made in the prostate and neck of the bladder is too small, great difficulty may be experienced in introducing the finger afterward; and in the child, where the connections of the bladder to the surrounding parts are very loose, the force made in the attempt is sufficient to displace the bladder upward into the abdomen, out of the reach of the operator. Such a proceeding has not unfrequently occurred, producing the most embarrassing results and total failure of the operation.

It is necessary to bear in mind that the arteries in the perinæum occasionally take an abnormal course. Thus the artery of the bulb, when it arises, as sometimes happens, from the pudic opposite the tuber ischii, is liable in its passage forward to the bulb to be wounded in the operation of lithotomy. The accessory pudic may be divided near the posterior border of the prostate gland, if this gland is completely cut across; and if the prostatic veins are of large size, and give rise, when divided, to troublesome hemorrhage. In men advanced in years the prostatic veins are very apt to be enlarged.

Extravasation of Urine.—Extravasation most commonly occurs from urethral rupture, between Colles's fascia and the triangular ligament of the urethra (extravasation *in front* of the triangular ligament). The adherence of these two fascial layers posteriorly prevents the urine from passing backward. The urine cannot find a way laterally, because both layers on each side are attached to the rami of the pubes and ischium. It cannot reach the pelvis, because the triangular ligament bars the way. It can only go forward if the two fascial layers remain intact, and consequently the urine passes into the areolar tissue of the scrotum beneath the superficial fascia of the penis and of the anterior abdominal wall.

Pus and blood would pursue the same course in this space. Effusions in this space causes much pain, because the space contains the three long scrotal nerves.

In rupture of the urethra between the two layers of the triangular ligament, the urine remains in this situation as long as fascia remains intact. If suppuration occurs, destruction of fascia liberates the urine.

In rupture behind the superior layer of the triangular ligament (extravasation back of the triangular ligament), the urine passes into the ischio-rectal fossa and upward and backward into the pelvis.

THE FEMALE PERINÆUM.

The female perinæum presents certain differences from that of the male, in consequence of the whole of the structures which constitute it being perforated in the middle line by the vulvo-vaginal passage.

The **Superficial Fascia**, as in the male, consists of two layers, of which the superficial one is continuous with the superficial fascia over the rest of the body, and the deep layer, corresponding to the fascia of Colles in the male, is, like it, attached to the ischio-pubic rami, and in front is continued forward through the labia majora to the inguinal region. It is of less extent than in the male, in consequence of being perforated by the aperture of the vulva.

On removing this fascia the muscles of the female perinæum, which have already been described (p. 461), are exposed (Figs. 311 and 1130). The Sphincter vaginae, corresponding to the Accelerator urinae in the male, consists of an atten-

uated plane of fibres, forming an orbicular muscle around the orifice of the vagina, instead of being united in a median raphé, as in the male. The Erector clitoridis is proportionately reduced in size, but differs in no other respect from the erector penis, and the Transversus perinaei is similar to the muscle of the same name in the male.

The triangular ligament (Fig. 1130) is not strongly marked as in the male. It transmits the urethra and the tube of the vagina.

The **Compressor Urethrae** corresponds with the Compressor urethrae in the male. It arises from the ischio-pubic ramus, and, passing inward, its anterior fibres blend with the muscle of the opposite side, in front of the urethra; its middle fibres, the most numerous, are inserted into the side of the vagina, and the posterior fibres join the central point of the perinæum.

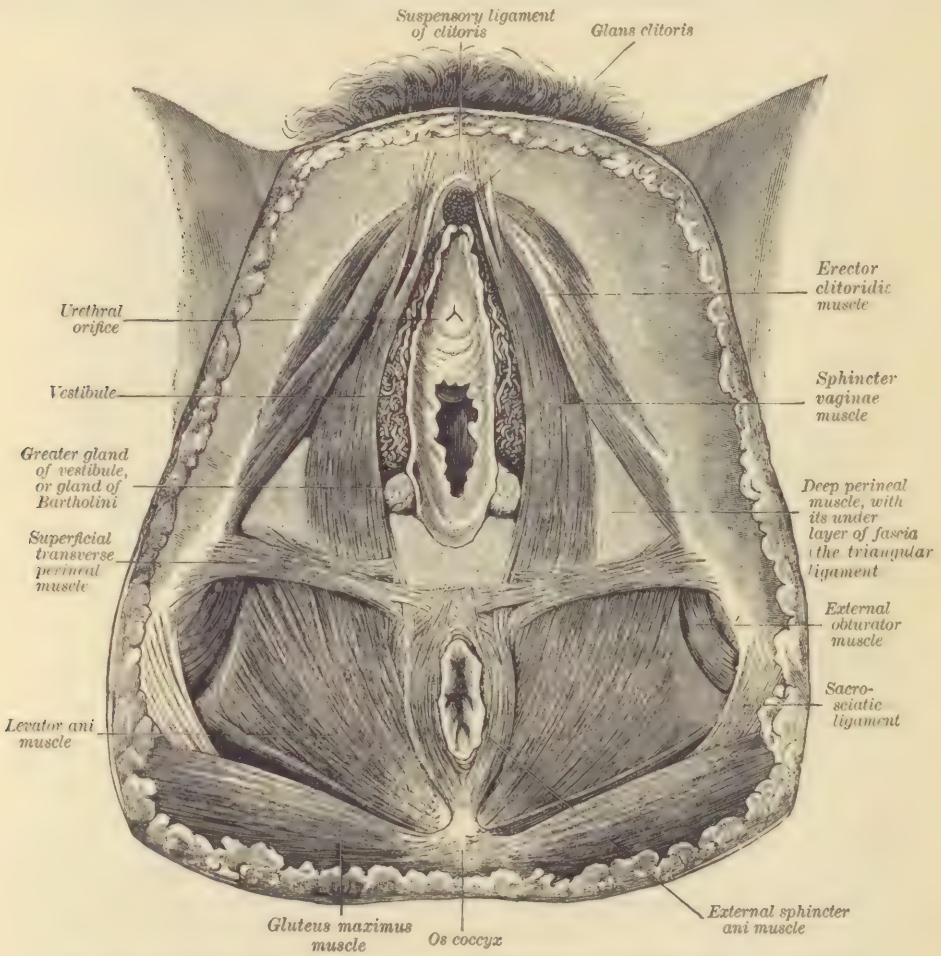

FIG. 1130.—The female perinæum after removal of the skin and superficial fascia. (Bardeleben.)

The distribution of the internal pudic artery is the same as in the male (p. 1540), and the pudic nerve has also a similar arrangement, the dorsal nerve being, however, very small and supplying the clitoris.

The corpus spongiosum is divided into two lateral halves, which are represented by the **bulbi vestibuli** and **partes intermediales**.

The **Perineal Body** fills up the interval between the lower part of the vagina and the rectum. Its base is covered by the skin lying between the anus and

vagina on what is called the **perinæum**. Its anterior surface lies behind the posterior vaginal wall, and its posterior surface lies in front of the anterior rectal wall and the anus. It measures about an inch and a quarter from before backward, and laterally extends from one tuberosity of the ischium to the other. In it are situated the muscles belonging to the external organs of generation. Through its centre runs the transverse perineal septum, which is of great strength in women, and forms on either side, behind the posterior commissure, a hard, ill-defined body, consisting of connective tissue, with much yellow elastic tissue and interlacing bundles of involuntary muscular fibres, in which the voluntary muscles of the perinæum are inserted.

The Pelvic Fascia (*fascia pelvis*) (Figs. 304 and 1131).—The pelvic fascia strengthens the floor of the pelvis, fastens pelvic structures together, and supports the nerves, blood-vessels, and lymphatics. It is connected above with the trans-

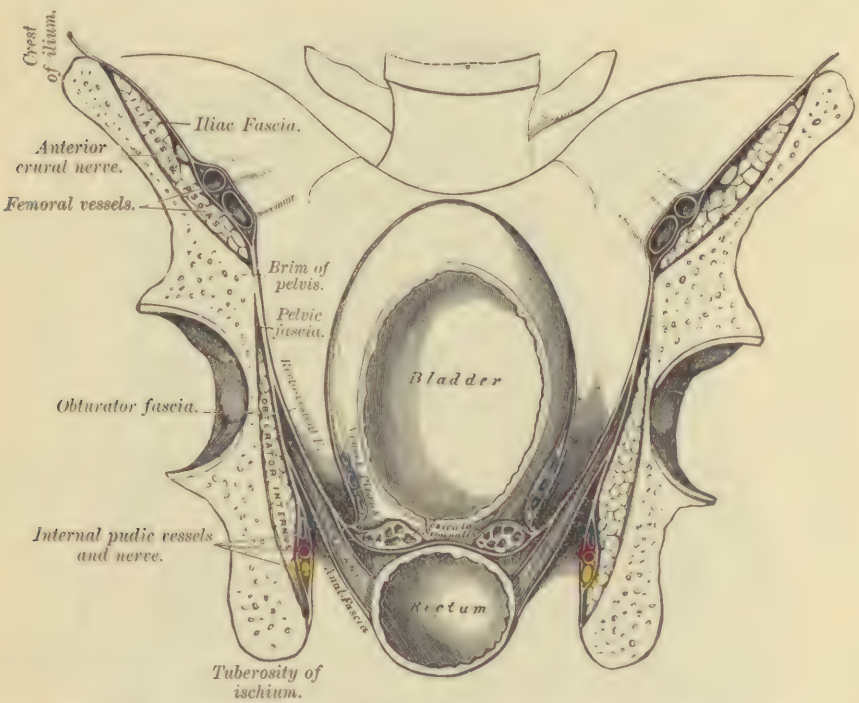

FIG. 1131.—A transverse section of the pelvis, showing the pelvic fascia from behind.

versalis fascia and the iliac fascia. It is at first a thin membrane and covers the inner surface of the pelvis, being attached to the brim for a short distance at the side of the cavity and to the inner surface of the bone around the attachment of the Obturator internus. At the posterior portion of this muscle it is continued backward as a very thin membrane in front of the Pyriformis muscle to the front of the sacrum. In front, as it descends, it gives off the **parietal layer of the pelvic fascia**, which continues as the **obturator fascia**. It then becomes thicker and covers the inner and upper surface of the Diaphragm of the pelvis as far as the **white line** (*arcus tendineus fasciæ pelvis*). The portion covering the superior and upper surface of the pelvic Diaphragm is the inner sheath of the Levator ani muscle and is called the **visceral layer of the pelvic fascia** or the **recto-vesical fascia** (*fascia diaphragmatis pelvis superior*). The white line is a rough band of fascial thickening, seen in the pelvic fascia of each side. It indicates the line of separation between the pelvic cavity and the ischio-rectal fossa. It passes from the lower

portion of the symphysis pubis outward and backward to the spine of the ischium. It makes the attachment of the Levator ani muscle to the pelvic fascia. At the white line the chief mass of the pelvic fascia passes upon the pelvic viscera and is known as the **fascia endo-pelvica.** It covers portions of the vagina, rectum, and urinary bladder, becomes thinner and thinner, and is gradually lost. Other bands of fascia begin at the white line, descend on the inner surface of the recto-vesical fascia, and in the male pass to the tip of the prostate and become the prostatic fascia. Between the anterior ends of the two white lines the level of the fascia is lower, and it forms a fossa, bounded on the sides in the male by the **pubo-prostatic ligaments** (*ligamenta puboprostatica lateralia*), and in the female by the **pubo-vesical ligaments** (*ligamenta pubovesicalia lateralia*). These ligaments are called the **lateral true ligaments of the bladder.** In the base of this fossa in the male runs the **anterior true ligament of the bladder** or the **pubo-prostatic ligament** (*ligamentum puboprostaticum*

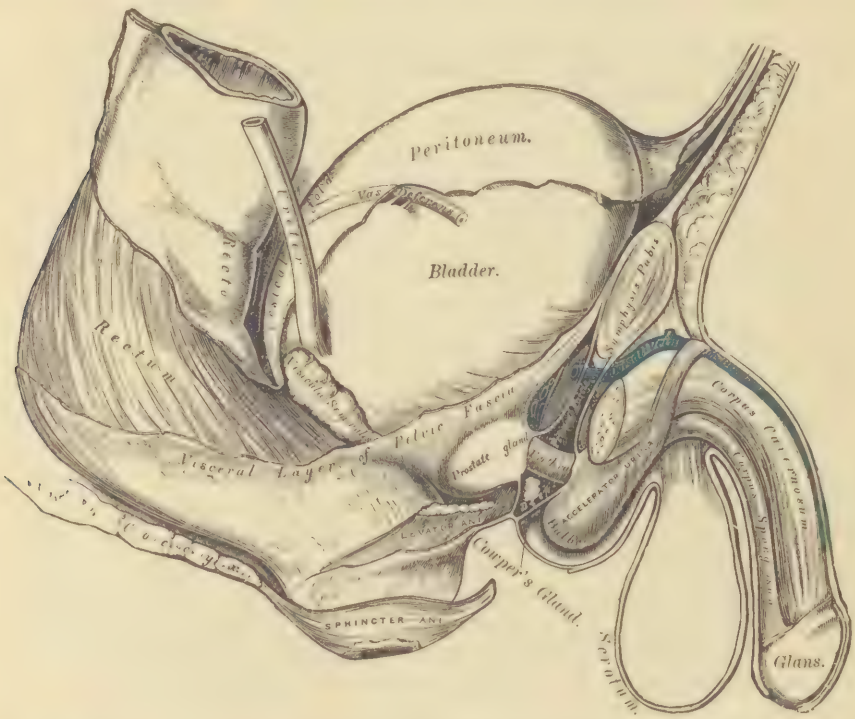

FIG. 1132.—Side view of the pelvic viscera of the male subject, showing the pelvic and perineal fasciae.

medium), and in the female the **anterior true vesical ligament** (*ligamentum pubovesicale medium*). These ligaments arise from the lowest portion of the symphysis and pass to the urinary bladder and prostate in the male, and urinary bladder and urethra in the female (Spalteholz). The outer surface of the pelvic Diaphragm is covered by the **anal fascia** or the **ischio-rectal fascia** (*fascia diaphragmatis pelvis inferior*). It is the lower or outer sheath of the Levator ani muscle, and is derived from the obturator fascia. The space between the obturator fascia and the anal fascia is pyramidal and is called the **ischio-rectal fossa** (*fossa ischiorectalis*).

The pelvic fascia does not completely invest the bladder, although the neck and lateral walls lie upon the Levator ani muscles, and the lateral true ligaments and the anterior ligament ascend upon the sides and front of the bladder and are lost upon the fibrous coat of that viscus. The sides and anterior wall have a fascial investment. The **sheath of the prostate** has already been discussed (p. 1449). It is

continuous with the recto-vesical fascia and the anterior true ligament of the bladder.

The pelvic fascia is composed, according to Hughes, of: 1. The fibrous capsules of the pelvic viscera. 2. The sheaths of the Levator ani and Coccygei muscles (recto-vesical and anal fasciæ). 3. The sheath of the Obturator internus (obturator fascia). 4. Sheath of the Compressor urethræ muscle (the triangular ligament). 5. The sheath of the pelvic aspect of the Pyriformis muscle. The sacral plexus is outside this sheath, the internal iliac vessels inside of it.[1] As previously stated, the pelvic fascia gives off the obturator fascia and the recto-vesical fascia.

The **Obturator Fascia** (*fascia obturatoria*) descends and covers the Obturator internus muscle. It is a direct continuation of the parietal pelvic fascia below the white line above mentioned, and is attached to the pelvic arch, the ischial tuberosities, and to the margin of the great sacro-sciatic ligaments. This fascia forms a canal for the pudic vessels and nerve in their passage forward to the perinæum, and gives off a thin membrane which covers the perineal aspect of the Levator ani muscle, and is called the **anal** or **ischio-rectal fascia.** It forms the inner boundary of the **ischio-rectal fossa.** From its attachment to the rami of the os pubis and ischium a process is given off which is continuous with a similar process from the opposite side, so as to close the front part of the outlet of the pelvis, forming the *deep layer of the triangular ligament.*

The **Recto-vesical Fascia** or **the Visceral Layer of the Pelvic Fascia** (*fascia endopelvica*) descends into the pelvis upon the upper surface of the Levator ani muscle, and invests the prostate, bladder, and rectum. From the inner surface of the symphysis pubis a short rounded band is continued, on each side of the middle line, to the upper surface of the prostate and neck of the bladder, forming the pubo-prostatic or anterior true ligaments of the bladder. At the side this fascia is connected to the side of the prostate, enclosing this gland and the vesico-prostatic plexus of veins, and is continued on to the side of the bladder, forming the lateral true ligaments of the organ. Another prolongation invests the seminal vesicle, and passes across between the bladder and rectum, being continuous with the same fascia of the opposite side. Another thin prolongation is reflected around the surface of the lower end of the rectum. The Levator ani muscle arises from the point of division of the pelvic fascia, the visceral layer of the fascia descending upon and being intimately adherent to the upper surface of the muscle, while the under surface of the muscle is covered by a thin layer derived from the obturator fascia, called the **ischio-rectal** or **anal fascia.** In the female the vagina perforates the recto-vesical fascia and receives a prolongation from it.

[1] A Manual of Practical Anatomy. By Prof. Alfred W. Hughes; edited and completed by Dr. Arthur Keith.

CHRONOLOGICAL TABLE

OF

THE DEVELOPMENT OF THE FŒTUS.

(From Beaunis and Bouchard.)

First Week.—During this period the ovum is in the Fallopian tube. Having been fertilized in the upper part of the tube, it slowly passes down, undergoing segmentation, and reaches the uterus probably about the end of the first week. During this time it does not undergo much increase in size.

Second Week.—The ovum rapidly increases in size and becomes imbedded in the decidua, so that it is completely enclosed in the decidua reflexa by the end of this period. An ovum believed to be of the thirteenth day after conception is described by Reichert. There was no appearance of any embryonic structure. The equatorial margins of the ovum were beset with villi, but the surface in contact with the uterine wall and the one opposite to it were bare. In another ovum, described by His, believed to be of about the fourteenth day, there was a distinct indication of an embryo. There was a medullary groove bounded by folds. In front of this a slightly prominent ridge, the rudimentary heart. The amnion was formed and the embryo was attached by a stalk, the allantois, to the inner surface of the chorion. It may be said, therefore, that these parts, the amnion and the allantois, and the first rudiments of the embryo, the medullary groove, and the heart, are formed at the end of the second week.

Third Week.—By the end of the third week the flexures of the embryo have taken place, so that it is strongly curved. The protovertebral disks, which begin to be formed early in the third week, present their full complement. In the nervous system the primary divisions of the brain are visible, and the primitive ocular and auditory vesicles are already formed. The primary circulation is established. The alimentary canal presents a straight tube communicating with the yolk-sac. The branchial arches are formed. The limbs have appeared as short buds. The Wolffian bodies are visible.

Fourth Week.—The umbilical vesicle has attained its full development. The caudal extremity projects. The upper and the lower limbs and the cloacal aperture appear. The heart separates into a right and left heart. The special ganglia and anterior roots of the spinal nerves, the olfactory fossæ, the lungs and the pancreas can be made out.

Fifth Week.—The allantois is vascular in its whole extent. The first traces of the hands and feet can be seen. The primitive aorta divides into aorta and pulmonary artery. The duct of Müller and genital gland are visible. The ossification of the clavicle and the lower jaw commences. The cartilage of Meckel occupies the first post-oral arch.

Sixth Week.—The activity of the umbilical vesicle ceases. The pharyngeal clefts disappear. The vertebral column, primitive cranium, and ribs assume the cartilaginous condition. The posterior roots of the nerves, the membranes of the nervous centres, the bladder, kidney, tongue, larynx, thyroid body, the germs of teeth, and the genital tubercle and folds are apparent.

Seventh Week.—The muscles begin to be perceptible. The points of ossification of the ribs, scapula, shaft of humerus, femur, tibia, palate, and upper jaw appear.

Eighth Week.—The distinction of arm and forearm, and of thigh and leg, is apparent, as well as the interdigital clefts. The capsule of the lens and pupillary membrane, the interventricular and commencement of the interauricular septum, the salivary glands, the spleen, and suprarenal capsules are distinguishable. The larynx begins to become cartilaginous. All the vertebral bodies are cartilaginous. The points of ossification for the ulna, radius, fibula, and ilium make their appearance. The two halves of the hard palate unite. The sympathetic nerves are now for the first time to be discerned.

[1] [Eternod (*Anat. Anzeiger*, Band xv., 1898) described an ovum which he reconstructed. It had a precise history, from which he concluded that it must have belonged to the end of the second or the beginning of the third week. Including the villi it measured $10 \times 8.2 \times 6$ mm. It was flattened on its embryonal side, and the embryo measured 1.3 mm. The amnion was completely formed and the allantois existed as a long canal. The vitelline circulation was established and the villi of the chorion were beginning to be vascularized. The blastopore still opened into the amniotic cavity, with the primitive groove behind it and the rudimentary groove in front. The notochord was closing in and all three layers of the blastoderm were distinct, except around the blastopore, where they formed an undivided mass.—Ed. of 15th English edition.]

Ninth Week.—The corpus striatum and the pericardium are first apparent. The ovary and testicle can be distinguished from each other. The genital furrow appears. The osseous nuclei of the bodies and arches of the vertebræ, of the frontal, vomer, and malar bones of the shafts of the metacarpal and metatarsal bones, and of the phalanges appear. The union of the hard palate is completed. The gall-bladder is seen.

Third Month.—The formation of the fœtal placenta advances rapidly. The projection of the caudal extremity disappears. It is possible to distinguish the male and female organs from each other. The cloacal aperture in divided into two parts. The cartilaginous arches on the dorsal region of the spine close. The points of ossification for the occipital, sphenoid, lachrymal, nasal, squamous portion of temporal and ischium appear, as well as the orbital centre of the superior maxillary. The pons Varolii and fissure of Sylvius can be made out. The eyelids, the hair, and the nails begin to form. The mammary gland, the epiglottis, and prostate are beginning to develop. The union of the testicle with the canals of the Wolffian body takes place.

Fourth Month.—The closure of the cartilaginous arches of the spine is complete. Osseous points for the first sacral vertebra and os pubis appear. The ossification of the malleus and incus takes place. The corpus callosum, the membrana lamina spiralis, the cartilage of the Eustachian tube, and the tympanic ring are seen. Fat is first developed in the subcutaneous cellular tissue. The tonsils are seen, and the closure of the genital furrow and the formation of the scrotum and prepuce take place.

Fifth Month.—The two layers of the decidua begin to coalesce. Osseous nuclei of the axis and odontoid process, of the lateral points of the first sacral vertebra, of the median points of the second, and of the lateral masses of the ethmoid make their appearance. Ossification of the stapes and the petrous bone and ossification of the germs of the teeth take place. The germs of the permanent teeth and the organ of Corti appear. The eruption of hair on the head commences. The sudoriferous glands, Brunner's glands, the follicles of the tonsil and base of the tongue, and the lymphatic glands appear at this period. The differentiation between the uterus and vagina becomes apparent.

Sixth Month.—The points of ossification for the anterior root of the transverse process of the seventh cervical vertebra, the lateral points of the second sacral vertebra, the median points of the third, the manubrium sterni and the os calcis appear. The sacro-vertebral angle forms. The cerebral hemispheres cover the cerebellum. The papillæ of the skin, the sebaceous glands, and Peyer's patches make their appearance. The free border of the nail projects from the corium of the dermis. The walls of the uterus thicken.

Seventh Month.—The additional points of the first sacral vertebra, the lateral points of the third, the median point of the fourth, the first osseous point of the body of the sternum, and the osseous point for the astragalus appear. Meckel's cartilage disappears. The cerebral convolutions, the island of Reil, and the tubercula quadrigemina are apparent. The pupillary membrane atrophies. The testicle passes into the vaginal process of the peritoneum.

Eighth Month.—Additional points for the second sacral vertebra, lateral points for the fourth and median points for the fifth sacral vertebræ, can be seen.

Ninth Month.—Additional points for the third sacral vertebra, lateral points for the fifth, osseous points for the middle turbinated bone, for the body and great cornu of the hyoid, for the second and third pieces of the body of the sternum, and for the lower end of the femur appear. Ossification of the bony lamina spiralis and axis of the cochlea takes place. The eyelids open, and the testicles are in the scrotum.

Vertex of skull, 129
Vertical lingualis muscle, 399
plate of palate bone, 117
Verumontanum, 1442
Vesical arteries, 686
plexus of nerves, 1086
of veins, inferior, 762
superior, 761
trigone, 1438
Vesicle, prostatic, 1442
Vesicles, Graafian, 1502
seminal, 1475
Vesico-uterine ligament, 1490
Vesicula prostatica, 1441
Vesicular column of Clark, 846
Vestibular artery, 1176
ganglion, 1053
nerve, 1053
path, 1054
root of eighth nerve, 1050
window, 1152
Vestibule, aortic, of Sibson, 572
of ear, 1164
of mouth, 1194
of nose, 1099
of vagina, 1481
Vestigial fold of pericardium, 561
Vibrissæ, 1096
Vicq d'Azyr, bundle of, 883
Vidian artery, 616
canal, 96, 135
nerve, 1034
veins, 730
Vieussens, ansa of, 1076
centrum ovale majus of, 881
valve of, 910, 933
Villi of small intestine, 1292
synovial, 262
Viscera, development of, 1235
Visceral cranium, 71
layer of pleura, 1382
lymphatics, 811
peritoneum, 1247
portion of tunica vaginalis, 1470
surface of liver, 1329
of stomach, 1270
Visual axis, 1106
centres, 1022
purple, 1120
Vitreous body, 1129
humor of eye, 1129
table of skull, 34
Vocal cords, false, 1370
true, 1370
process, 1365
Voice, organs of, 1361
Volkmann's canals, 38
Voluntary muscle, 361
Vomer, 120
lake of, 121, 143
articulations of, 122
development of, 122
surfaces of, 121
Vomerine cartilage, 1097
Vortex of heart, 575
Vulva, fossa navicularis of, 1478
Vulvo-vaginal gland, 1482

W

Waldeyer, germ[illegible]
of, 1501
odontoblasts of
Wedge bones, 24
-shaped funicu
Wharton's duct
White commiss
fibrous tissue
line of Hilton
matter of cerebe
of cerebrum, 913
nerve fibres, 822
substance of cord, 841
of Schwann, 822
Willis, circle of, 629, 640
Winslow, accessory anterior crural nerve of, 1004
ligament of, posterior, 335
uncinate process of, 1348
Wirsung, canal of, 1351
Womb, 1486
Worm of cerebellum, 926
Wormian bones, 103
development of, 103
Wrisberg, cardiac ganglion of, 1081
cartilages of, 1365
cuneiform tubercle of, 1368
ligament of, 339
nerve of, 986
pars intermedia of, 1045
Wrist, articulations of, 317
bursa of, 492
-joint, 317
ligament of, 318
surface form of, 318
surgical anatomy of, 318

X

Xipho-pericardial ligament, 559
Xiphoid appendix, 158
surfaces of, 158
cartilage, 155

Y

Y-ligament, 328
Yellow elastic tissue, 261
spot of Sömmerring, 1121

Z

Zinn, ligament of, 373
zonule of, 1129
Zona arcuata, 1173
fasciculata, 1430
glomerulosa, 1430
incerta, 910
orbicularis, 327
pectinata, 1173
reticularis, 1430
tecta, 1173
Zonula ciliaris, 1129
Zonule of Zinn, 1129
Zygoma, 84
Zygomatic arch, 138
fossa, 138
lymphatic glands, 782
process of malar, 115
of temporal bone, 94
Zygomaticus major muscle, 377
minor muscle, 377
Zymogen granules, 1352
